Cases of septic endocarditis belong to one of three categories as follows: Acute septic endocarditis, chronic septic endocarditis, and the so-called endocarditis lenta caused by the *Streptococcus viridans*. In the acute type the cases run their course in a few days or weeks and are almost invariably fatal. In most instances the seat of the disease is the left side of the heart, more particularly the mitral valve. Auscultation may reveal any of the various types of murmurs, none of which is characteristic, nor is the loudness of the murmur parallel with the intensity of the inflammation. As a rule the endocarditis is accompanied by a myocarditis; sometimes the pericardium is involved. The bacterial toxins produce a central vasomotor paralysis with a resulting marked diminution in blood pressure. Dilatation of the heart is a natural sequence of the myocarditis. The pulse is increased in frequency and corresponds to the height of the temperature. Thrombophlebitis and septic arteritis are frequent accompaniments. The temperature curve may assume the most varied types; it may resemble that of typhoid fever; it may be remittent or intermittent, and chills may usher in the disease and may be repeated frequently during its course. Collapse is often indicated by a sudden drop in the temperature. Embolic processes in various parts of the body are a common sequence of septic endocarditis. Important points in the diagnosis of this condition are the necrotic patches in the retina which are present in one-third of the cases, and the purpuric and other cutaneous eruptions which are the result of bacterial emboli in the skin. Arthritic manifestations are very common in this disease. A striking pallor of the skin is to be noted in most of the cases, and very frequently an icteric tinge of the skin and mucosa is to be observed.

Chronic septic endocarditis may run a course of several months' duration. It is caused most frequently by the streptococcus. Endocarditis lenta is characterized by its insidious course. Lenhartz and Schottmüller have shown that is its caused by the *Streptococcus viridans*. The peculiarities of this type of endocarditis are the following: There is almost always a history of articular rheumatism. In the beginning the patient complains of headache, dizziness, wandering pains in the joints, and chilly sensations. In the presence of these symptoms the diagnosis of influenza is often made. There may be only a gradually increasing lassitude, a pallor, and a breathlessness on exertion; otherwise, there may be no subjective disturbance and the disease may run its latent course until an embolus produces the first objective manifestation of the endocarditis. In other cases the picture may be that of acute articular rheumatism. The portal of entry of the *Streptococcus viridans* is in most instances the mucous membrane of the upper respiratory tract, particularly of the tonsils. Sometimes the infection starts in a tooth abscess. When fully developed the disease presents the following clinical picture: The temperature oscillates between 37° and 38.5° Centigrade. There is a characteristic waxen subicteric tinge of the skin. There is a progressive reduction in the erythrocytes and the hemoglobin percentage. In most of the cases there is a leucocytosis; in some instances, however, there is a leucopenia. Occasionally there is a pronounced tenderness on pressure over the sternum.

The valves most frequently affected are the mitral and the aortic. The resulting murmurs are usually distinct, but there are some cases in which no murmurs are evident. In these cases the fever persisting for several weeks, the swelling of the spleen, and anemia in association with possibly other septic symptoms may suggest the presence of a septic endocarditis. The diagnosis is made certain only with the aid of blood culture. The *Streptococcus viridans* may be isolated from the blood in 90 per cent of the cases. In spite of this bacteriemia the patient may be in relatively good condition for as long as ten months. Towards the end, however, the appetite fails and the signs of cardiac insufficiency arise. The septic emboli and infarcts at this stage of the disease give to it a most diverse picture.

The disease is almost invariably fatal. Cases have been reported in which the patients apparently recovered with a disappearance of the microorganisms from the blood, but succumbed later to the sequelæ of the endocarditis, such as embolism and nephritis. The treatment is apparently without avail. Neither specific sera nor vaccines have given

any encouragement in the hands of Jochmann, though Gilman Thompson of New York has reported three cases of recovery out of seven in which vaccines were employed.

DELAYED CHLOROFORM POISONING.

THE pathological condition which may develop following the prolonged administration of chloroform is comparatively familiar and the edema, fat infiltration, multiple hemorrhages, and necrosis of the central portion of the liver lobule have been recognized as characteristic if not pathognomonic of this condition. The subject has been quite extensively studied in one aspect or another and much is known about the condition, but the factors involved in its development and production have never been investigated satisfactorily. The theories proposed have not found general acceptance because of the grave objections which have been offered to all of them.

A recent attempt to solve the problem has apparently met with more success. Graham (*Jour. Exper. Med.*, 1915, xxii, 48) bases his theory upon the well known fact that chloroform is quite easily oxidized to phosgene and hydrochloric acid, and the former in the presence of water is decomposed into carbon dioxide and hydrochloric acid. This process takes place spontaneously unless the chloroform is protected from oxidation in some manner. Commercially, such protection is furnished by adding alcohol to the chloroform. The alcohol has a greater affinity for the oxygen than chloroform and so protects it from oxidation. Graham reasoned that if oxidation were so easy *in vitro* it would probably occur to a certain extent in the body and that the lesions of chloroform poisoning might be due to the action of the hydrochloric acid which was thus set free. The administration of hydrochloric acid to animals both orally and into the portal vein produced all the pathological characteristics of chloroform poisoning except that the necrosis occurred in the periphery of the liver lobule rather than the central portion. In animals killed forty-eight hours after prolonged chloroform anesthesia, the attempt to demonstrate hydrochloric acid in the liver lesion was not successful although there was evidently an increase in the amount of acid present. This difficulty is not surprising, for chlorine ions are always normally present. As indirect evidence, however, it has been shown that the excretion of neutral inorganic chlorides in the urine is increased after the administration of chloroform. Graham then investigated other substances which might set free hydrochloric acid in the body and found that the administration of mono-, di-, and tetra-chlormethane resulted in similar lesions and that the severity of the condition was exactly proportional to the amount of chlorine in these compounds. Since other alkyl halides might be expected to act in an analogous manner, though they might set free hydrobromic or hydriodic acid, the investigation was extended to include iodoform, bromoform, ethyl bromide, ethyl iodide, ethyl chloride, and ethylene bromide, and in every instance the lesions found at autopsy corresponded to those found in chloroform poisoning. The administration of ether and chloral, on the other hand, does not produce such lesions and these substances do not set free hydrochloric acid in their decomposition. As further confirmatory evidence he was able to prevent or lessen the severity of the lesions produced by the intravenous administration of Fisher's alkaline solution at the time of the anesthetic.

It may be objected that all of the evidence is indirect, yet the nature of the problem is such that only indirect evidence is obtainable. Certainly the observations all tend to support the idea "that the halogen acid (hydrochloric, hydrobromic, or hydriodic acid), directly liberated in the process of dissociation, may be the important factor which makes the tissue changes seen in poisoning with chloroform and other alkyl halides so different from those following the administration of narcotic drugs of a different type. One interesting fact noted was that in the animals which received protective doses of alkali the beneficial results were particularly striking in the kidneys. In the control animals which received no alkali, these organs were always enormously swollen and weighed much more than those of the alkali animals. The effect of the alkaline hypertonic salt solution in inhibiting the swelling of the kidneys tends strongly to support Fisher's theories as to the nature and origin of edema. The question of the pathological production of acid is assuming an important position in the domain of pathological physiology. The problem is an obscure one and definite experimental results are difficult of attainment so that such reports as these are the more welcome. The practical application is clear, though the value of alkali administration after the onset of symptoms is wholly unknown and may be very slight.

MALAY MEDICINE MEN.

THE therapeusis of the native practitioners in Malaysia does not differ much from that in vogue among the "medicine men" of the American Indians, if we are to believe Dr. J. D. Gimlette[1], who has worked among them for eighteen years. Disease, according to the Malays, is due to magic influences and hence is amenable to magic. It is a sort of spell or baleful influence cast upon the afflicted individual by jinn, devils, or ghosts. In the Malay Materia Medica noise takes the place of nux vomica. If the witch doctor is not sure just which evil spell has his patient in its grip he makes plenty of noise on general principles hoping that this will scare away the malign influence. If he is able to diagnose the case accurately, however, and determine just which familiar is preying upon the victim he selects the incantation which the wisdom of his forefathers or perhaps their dealings with the powers of darkness have discovered and pronounces this with all due form and ceremony. If the demon is properly intimidated he slinks away forthwith, but if not—well, the witch doctor is too much feared himself to fear non-payment from the survivors. These witch

1. *Malay Poisons and Charm Cures*, by J. D. Gimlette, M.R.C.S., L.R.C.P. London: J. A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1915.

doctors are usually very old men, old not only in years but in cunning.

Poisoning is quite common among the Malays, but, contrary to the general belief, is not practised with any degree of finesse. Poisons are part of the regular armamentarium of thieves who prefer to stupefy their victims in some way before proceeding with the work of plunder. For this purpose they most commonly use the seeds of the datura plant, which contain hyoscine. About fifty of these seeds are given in tea or coffee, the equivalent of approximately one-fortieth grain of hyoscine; or the drug may be burned in a room directly below the one occupied by the prospective victim, who is overcome by the fumes. The effect of the poison administered in either of these two ways is transitorily unpleasant but rarely fatal.

A poison derived from the upas tree is a great favorite with Malay malefactors and here again we meet with a fairly widespread erroneous belief. The exhalations of this tree were formerly thought to be so deadly that no animal life could survive within fifty yards of it. Even nowadays many think that the upas tree is the most poisonous member of the vegetable kingdom. There is a story to the effect that when the poison from this tree is wanted, twenty condemned criminals are sent for it. Usually only one or two return alive and these are pardoned. As a matter of fact, the upas tree itself may be chopped down by anyone with a sufficiently good axe and stout biceps. The juice of the tree contains a glucoside which has an action on the heart almost exactly resembling that of digitalis or strophanthus. The Malay smears his creese or arrow with the inspissated juice and if the wound made by one of these is sufficiently deep enough of the poison enters the system to produce a toxic effect on the heart which is paralyzed in systole. Although the Malays are well versed in the uses of their native poisons they have practically no knowledge of antidotes. Their only remedy seems to be the fresh juice of the cocoanut, which is slightly acid and diuretic, but appears to have no especial therapeutic action.

The Malays are subject to a peculiar psychotic phenomenon and also to a neurotic one. Among them conditions which in a civilized people would probably lead to suicide make the individual "run amuck," that is, he arms himself and runs wild, killing everyone he meets until he is himself killed. A neurotic disturbance known as the latah is prevalent among them. This seems to be practically the same as the "jumping disease" of the woodsmen of Maine and Canada and the miryachit of the Orientals.

Syphilis in the Navy.

Metchnikoff's method for preventing syphilis by applying calomel ointment immediately after exposure to infection has reduced the incidence of syphilis in the navy during the past six or seven years, but the reduction has not been so great as was anticipated. Syphilis still almost heads the list of those diseases which cause a large number of sick days. G. P. Cottle, Passed Assistant Surgeon, U. S. N., writing in the *Naval Medical Bulletin* for July, 1915, says that it is to be hoped that in time the bureau will issue neosalvarsan or salvarsan to every ship and station. Several years' experience with these drugs has demonstrated to Cottle that their administration on board ship or at stations and yards is as practicable as at a hospital. The apparatus needed is simple and found in the regular armentarium, and the drug is safe enough if a simple aseptic technique and reasonable care be used. According to the writer, in order to gain a reduction in the damage done by syphilis in the navy, early exact diagnosis and intensive salvarsan-mercury treatment are the essentials, but these essentials though simple to state are difficult to attain. The delay in reporting venereal disease by the sufferer until it is too late to make an early diagnosis from the primary lesion is responsible for many cases not being treated in time. On board ship persistence is necessary to make inspection efficient and complete. In conclusion, it is believed that sick days in hospital for this class of patient should be reduced to a minimum; that except in unusual cases syphilis should be treated aboard ship or at the station or yard; that early discovery of the treponema is now practicable; that neosalvarsan should be issued to ships and stations and that the measures above mentioned, if properly carried out, will increase naval efficiency and do much toward removing the unnecessary losses in sick days now yearly charged to syphilis.

Suspected Typhus.

The diagnosis of suspected diseases has never been elevated to a special discipline of medical teaching, although health officers are supposed to follow certain rules in isolating subjects for observation, a history of exposure being the most obviously necessary. When a disease like typhus menaces a community suspects will be in evidence, and a history of exposure cannot perhaps be obtained. In order not to work hardships on the innocent, certain criteria of due cause for suspicion should be postulated. At a recent session of the Hamburg Medical Society (*Berliner klinische Wochenschrift*, June 7) Becker cites the case of a seamstress who had been seized with chill and headache. Numerous petechiæ and actual hemorrhages were found in the integument. There were stiff neck and a weak, positive Kernig sign, and splenic tumor was absent. The patient developed notable somnolence. The diagnosis of cerebrospinal meningitis was verified later by lumbar puncture. Every patient who presents symptoms suggestive of beginning meningitis may be held suspected of typhus until differential diagnosis is possible. Naturally, however, such a patient would require isolation even without suspicion of typhus. In another case the initial symptoms were common alike to typhus and typhoid. The agglutination and diazo tests spoke for the latter, but the patient had been recently inoculated against it. Again it was impossible to cultivate typhoid bacilli from the blood. The true diagnosis —typhus—was established by the subsequent course of of the disease. Hence in a typhus menace any case of typhoid fever without enteric manifestations should be regarded as suspicious, for the general phenomena of the two diseases may parallel each other while the serodiagnostic tests may fail.

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the following contributions received during the week ending August 7, 1915:

Marwick, Mitchell, Peat & Co., Chartered Accountants. Three audits of the Treasurer's accounts, March 20, May 30, and June 20, 1915.	
Dr. E. W. Smith, Meriden, Conn.	$10.00
Receipts for the week ending August 7	$10.00
Previously reported receipts	7,769.84
Total receipts	$7,779.84

Cholera in Austria-Hungary.—A cable report early this week stated that an epidemic of cholera was prevailing in Vienna, over 500 new cases occurring each day in that city, and that the ravages of the disease were even greater in Budapest. The epidemic is said to be spreading also in the eastern provinces, especially among the troops in Galicia.

Gift of an Ambulance to the Bavarian Army.—A dispatch from Berlin states that Mrs. Jessie Stillman Taylor of New York, who has resided in Munich, has presented an ambulance train to the Bavarian army. It consists of a motor ambulance and two trailers.

Health of New York City.—The Department of Health reports a total of 1,328 deaths in this city during the week ending July 31, giving a death rate of 11.94 as compared with 11.67 during the week preceding and 12.06 during the corresponding week in 1914.

Health of Chicago.—During the week ending July 31 there were 490 deaths in Chicago, giving a rate of 10.4 per thousand of estimated population, as compared with 10.8 for the preceding week and 12.9 for the corresponding week in 1914.

Enforcing the Registration of Births.—Active steps are being taken by the New York State Department of Health to enforce the law requiring the report by physicians of births within five days after they occur. Dr. Hermann M. Biggs, State Commissioner of Health, has sent to district attorneys throughout the State lists of physicians who have been persistently negligent in this matter, and the county prosecutors have been asked to warn the offending physicians that further infractions of the law will be promptly prosecuted. The State law provides that, upon conviction a physician or other violator of the Vital Statistics article of the Health Law "shall for the first offense be fined not less than $5 nor more than $50, and for each subsequent offense not less than $10 or more than $100, or be imprisoned in the county jail not more than sixty days, or be both fined and imprisoned, in the discretion of the court."

Federal Investigation of Occupational Diseases in Pittsburgh.—Officers of the U. S. Public Health Service in Pittsburgh have recently established a bureau for the study of occupational diseases and will begin by investigating the relation of workers' fatigue to temperature and humidity in the mills in that district. They will also study the effect of poisonous gases and fumes upon the general health of workmen, condition of workers, light used in mills and shops, ventilation, length of working hours, time spent going and coming from work, exposure to dust, water supply, and sanitary conditions.

Medical Education in China.—Four members of the China medical board of the Rockefeller Foundation sailed last week on the *Tanyo Maru* of the Japanese line from San Francisco to reorganize the Union Medical College at Pekin, the Foundation having bought the largest hospital in China for use as a center of a system of medical schools. Those going to China are Dr. Wallace Buttrick, director of the board; Dr. Simon Flexner, director of laboratories of the Rockefeller Institute for Medical Research; Dr. William H. Welch, professor of pathology at Johns Hopkins University, and Dr. J. C. Cater, Jr.

The New York State Veterinary College will soon, it is announced, be moved from its present location in West Fifty-fourth Street to the quarters of the University and Bellevue Hospital Medical College. The work can there be more closely correlated than in the past with the work of the medical college. A piece of land adjacent to the medical college and belonging to the University has been set aside for the new veterinary building. The course of instruction will at the same time be extended from three to four years and the requirements for admission and graduation will be raised.

The Washington State Medical Society held its annual session in Tacoma on July 21 and 22. The following officers were elected: *President*, Dr. J. M. Semple of Spokane; *First Vice-President*, A. E. Burns, Seattle; *Second Vice-President*, C. Stuart Wilson, Tacoma; *Secretary*, C. H. Thompson, Seattle; *Assistant Secretary*, J. H. O'Shea, Spokane; *Trustees*, W. M. Hunt, L. M. Sims, H. H. McCarthy, C. J. Lynch; *Journal Trustees*, Wilson Johnson, E. W. Janes, P. D. McCormick; *Delegate to the American Medical Association*, Dr. Don Palmer, Seattle; *Alternate*, Dr. E. M. Eikenbary. The next annual meeting will be held in Seattle.

The Medical Society of the Missouri Valley will hold its twenty-eighth annual meeting in Des Moines, Iowa, on September 23 and 24, 1915, under the presidency of Dr. Granville N. Ryan of Des Moines. The secretary of the society is Dr. Charles Wood Fassett of Kansas City, Mo. The oration in surgery will be given by Dr. John B. Murphy of Chicago, on the evening of the first day, and on the second day Dr. George W. Crile of Cleveland will deliver an oration on cancer of the pylorus.

A Grievance.—The French-speaking physicians in a manufacturing town in Massachusetts, at a recent meeting, adopted a report to the effect that they were systematically slighted by their ex-patients' families. In the published card of thanks after a funeral, the report stated, one "will find that everybody connected with the sad ceremonial, the bearers, the priest, and undertaker, come in for their share of thanks, the doctor alone appears to be forgotten." In lieu of the gratitude which was wanting they decided to raise their charges and established a rate of $1.50 for a day visit and $2.50 for a night visit with a flat rate of $10 for a confinement of ordinary length and $2 an hour additional if the labor was unduly prolonged.

The Boston Health Commissionership.—Dr. Richard H. Creel of the U. S. Public Health Service, who was recently appointed Health Commissioner of Boston by Mayor Curley, has declined the offer. He gives as reason for his refusal the state of his health and his belief that the administration of the Boston department is already so efficient that he could do little to improve it. Two days after this declination was announced Dr. William J. Gallivan, who was health commissioner of Boston, presented his resignation, which was accepted by the Mayor.

Dr. Otto V. Huffman, formerly secretary of the New York State Board of Medical Examiners and secretary-treasurer of the Federation of State Medical Boards, has moved from Albany to his new residence at 89 Joralemon Street, Brooklyn, N. Y. Dr. Huffman has accepted the lecturership on physical diagnosis at the Long Island College Hospital, and is also the secretary and executive head of the college faculty. No successor to the position left vacant at Albany has yet been appointed. Dr. Walter L. Bierring, president of the Iowa Board, succeeds Dr. Huffman in the Federation and will be the editor of the Federation's *Monthly Bulletin.*

Eucalyptus in Meningitis.—A dispatch from Melbourne, Australia, states that Dr. Richard Bull, director of the bacteriological laboratory in the University of Melbourne, claims to have discovered in eucalyptus a specific remedy for epidemic cerebrospinal meningitis. Details as to preparation, dosage, and mode of administration are not given.

Charitable Bequests.—By the will of the late Sarah E. Batterson, formerly of Philadelphia, and who died recently at Rockingham, Mass., bequests are made as follows: St. Mary's Free Hospital for Children, New York, $10,000; Clarkson Hospital, Omaha, Neb., $2,000; Sanitarium Association of Philadelphia, $3,000; Children's Seashore Home, Atlantic City, $3,000; Women's Seashore Home, Atlantic City, $3,000.

By the will of the late Anna Yarnall, of Philadelphai a residuary bequest of $5,000 is made to the Women's Medical College.

Mrs. Elizabeth Sprague Coolidge of Pittsfield and Chicago has given $100,000 to the Pittsfield Anti-Tuberculosis Association as a memorial to her husband, the late Dr. Frederick S. Coolidge. This fund is to be held in trust for a new building to be known as "the Frederick Shurtliff Coolidge Memorial Home."

By the will of the late Elizabeth M. D. Prince of Philadelphia, the residue of her estate, amounting to $4,300, is bequeathed to the German Hospital as a memorial to her father, Henry W. Enternach.

Medical Society Elections.—The Franklin County, Vt., Medical Society met in Burlington on July 13 and elected the following officers: *President*, Dr. C. G. Abell of Enosburg Falls; *Vice-President*, Dr. E. A. Hyatt of Burlington; *Secretary and Treasurer*, Dr. W. J. Upton of Burlington. Dr. Robert W. Lovett of Boston read a paper on the poliomyelitis epidemic in Vermont in 1914.

The North Carolina State Medical Society, at its annual meeting held in Greensboro June 16, elected the following officers: *President*, Dr. Marshall H. Fletcher, Asheville; *Vice-Presidents*, Drs. James L. Nicholson, Richlands, L. N. Glenn, Gastonia, and W. H. Hardiston, Cresswell; *Secretary*, Dr. Benjamin K. Hays, Oxford; *Treasurer*, Dr. William M. Jones, Greensboro. The next meeting will be held at Durham in April, 1916.

The Association of Surgeons of the Southern Railway, meeting in Asheville, June 2 to 5, elected the following officers: *President*, Dr. Lane Mullally, Charleston, S. C.; *Vice-Presidents*, Drs. B. M. Tittsworth, Jefferson City, Tenn.; Stephen Harnsberger, Catlett, Va.; H. H. Briggs, Asheville, N. C., and W. H. Hutchinson, Childersburg, Ala., and *Secretary-Treasurer*, Dr. J. U. Ray, Woodstock, Ala. (re-elected). Chattanooga, Tenn., was selected as the next meeting place.

The Southwestern Virginia Medical Society, at its annual meeting held in Wytheville June 24 and 25, elected the following officers: *President*, Dr. W. K. Vance, Bristol; *Vice-Presidents*, Drs. J. C. Motley, Abingdon, and G. G. Painter, Pulaski; *Secretary-Treasurer*, Dr. A. B. Greiner, Rural Retreat.

The Rutland County, Vt., Medical Society, at its annual meeting at Lake Bomosen on July 13, elected the following officers: *President*, Dr. C. E. Griffin, Fair Haven; *Vice-President*, Dr. J. S. Eastwood, Brandon; *Secretary and Treasurer*, Dr. F. H. Gebhardt, Rutland; *Auditor*, Dr. C. S. Caverly, Rutland; *Censors*, Drs. M. R. Crain, Rutland, G. D. Parkhurst, Fair Haven, and J. W. Estabrook, Brandon; *Delegates to the Vermont Medical Society*, Drs. E. S. Crowfut, Poultney, T. H. Hack, Proctor, and C. H. Swift, Rutland.

Obituary Notes.—Dr. Carl F. Kremer of New York, a graduate of the University of Griefswald, Germany, in 1867, a member of the New York Academy of Medicine, and for many years on the staff of the German Hospital, New York, died at his country home in White Plains, N. Y., on July 17, aged 73 years.

Dr. Charles Parker Hooker of Springfield, Mass., a graduate of the Harvard University Medical School, Boston, in 1879, and a member of the American Medical Association, the Massachusetts Medical Society, and the Hampden District Medical Society, died at his summer home in Biddeford, Me., on July 21, aged 60 years.

Dr. Joseph Sherrill Leech of Glasgow, Ky., a graduate of the University of Louisville, Medical Department, in 1881, a member of the Kentucky State Medical Association and the Barren County Medical Society, and Mayor of Glasgow, died at his home on July 10, aged 57 years.

Dr. Thomas Sparrow Burbank of Wilmington, N. C., a graduate of Bellevue Hospital Medical College, New York, in 1886, and a member of the American Medical Association, the Medical Society of the State of North Carolina, and the New Hanover County Medical Society, died at his home, after a long illness, on July 12, aged 61 years.

Dr. Abraham T. Dewitt died at South Danville, Pa., on July 22, at the age of 74 years. He was graduated from the Medical Department of the University of Vermont in the class of 1862, and he served as Surgeon to the Third Pennsylvania Artillery during the Civil War. He was also a member of the State Legislature for two terms from 1872.

Dr. Jacob H. Frankenberg of New York, a graduate of the College of Physicians and Surgeons, New York, in 1883, and a member of the New York State and County Medical Societies, died at his summer home in Cedarhurst, Long Island, from heart disease, on July 27, aged 53 years.

Dr. Thomas H. White died at Connellsville, Pa., on July 13 at the age of 70 years. He was graduated from Jefferson Medical College in the class of 1870. He was a member of the Fayette County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. James Goldlust of New York, a graduate of the New York University Medical College, New York, in 1894, physician to the Mt. Sinai Hospital Dispensary, and a member of the New York State and County Medical Societies, died at his home on July 27, aged 48 years.

Obituary.

P. BRYNBERG PORTER, M.D.

NEW YORK.

DR. P. BRYNBERG PORTER died in St. Mark's Hospital on Friday of last week, after a brief illness, at the age of 69 years. He was graduated from the Medical Department of the University of Pennsylvania in 1869 and began practice in Wilmington, Del., but removed to this city forty years ago. He was a member of the Medical Societies of the State and County of New York and of the American Therapeutic Association, and had been an active member and secretary of the Medical Association of the Greater City of New York since its foundation. He was also assistant secretary of the American Congress of Physicians and Surgeons. He was a member of the editorial staff of the *New York Medical Journal* and was also a valued contributor to the MEDICAL RECORD.

Correspondence.

OUR LONDON LETTER

(From Our Regular Correspondent.)

IN PARLIAMENT—TAXING HOSPITALS—MEDICAL ARRANGEMENTS IN THE NAVAL AND MILITARY FORCES—ANTI-TYPHOID INOCULATION—WOUNDED FROM THE DARDENELLES—ROYAL COLLEGE OF PHYSICIANS ON CRIMINAL ARORTION—MOTHERCRAFT EXHIBITION

LONDON, July 23, 1915.

PARLIAMENT has recently had before it quite a number of questions of considerable medical interest. Among them, whether the tax on hospitals, inflicted by the duty on spirits, should not be remitted. The increased cost of necessaries in this war time coincides with a diminution of subscriptions brought about by the same agency. This not only enforces the most rigid economy, but has for some time been holding before the managers of many institutions the proposal of compulsory closure by exhaustion of funds. Not that contributors have become less charitable, but their sympathies have been more and more drawn to the sick and wounded, so that in many cases the sums usually devoted by them to hospitals have been applied to the insistent calls on behalf of victims of the war.

In the House of Commons a proposal was made that the duty on spirits used in hospitals for the preparation of tinctures and other medicines should be remitted. This tax amounts to more than might be anticipated. Last year one hospital (the London) paid £229 for duty on spirits. It might be supposed that such an exemption would not be opposed, but objection was taken on the ground of some difficulties about defining a hospital so as to exclude nursing homes or any institutions run for a profit, or by the public authorities, as, for example, workhouse infirmaries. It was also said that the concession would lead to increase of the alcoholic medicines used, and of course the temperance party feared this. The clause was withdrawn with the intimation that it will be brought forward again. In reply to a question in the House, it was stated that the new medical arrangement at the royal naval hospital is that seven consultants should be given temporary commissions as surgeons-general, with the pay and allowances of that rank; two others as fleet-surgeons of ten years' seniority, with corresponding emoluments. Another question was put as to a case in which a panel committee had surcharged a medical officer on account of cost of drugs exceeding that allocated under the act. The answer was that the practitioner had a right of appeal. Of antityphoid inoculation, it was replied to a question that in the expeditionary force in France up to May 22 there had been 297 cases of paratyphoid, with ten deaths. During the whole of the campaign, from the beginning of August and so including a period when many of the men had not been inoculated, 827 cases of typhoid, with 128 deaths, have been recorded; 508 of the uninoculated, 106 fatal; of the inoculated 319, of which 22 were fatal.

The Medical Advisory Board, which was instituted by Lord Middleton, is said to be in constant touch with the medical director-general of the army, as also are the members of the two bodies, although they have no regular meetings. It would seem that there is hardly any need for both, and that the two might as well be amalgamated. Some discontent has been expressed at the anomalies as to pay in the different services. For example, the pay of a medical officer under special contract, with the temporary rank of lieutenant, is higher than the pay and allowances drawn by a captain in the R. A. M. C. It is asserted that the point is being considered by the authorities.

Some of the wounded from the Dardenelles on arrival in Alexandria were sent to the German Hospital, and the Secretary for War was questioned about it in rather hostile fashion. He declared the officer commanding in Egypt exercised a wise discretion in availing himself of the suitable accommodation ready at the German hospital, and no doubt if he had not done so he would have been criticized just as adversely as now.

Complaints have been made of the compulsory transfer of men from the R. A. M. C. to the fighting units, in view of the well understood fact that their object in joining the corps was solely to help the sick and wounded at the front. The War Secretary, being questioned in the House, said it was no longer necessary for members of the territorial force to undertake the liability of transference, but as to the regulars no alleviation was contemplated.

The Royal College of Physicians has had under consideration a question which may at any time present itself to a practitioner as to his duty in relation to criminal abortion. The question has often been a source of no little anxiety, and the conclusions of the college will no doubt exercise great influence, and may therefore be summarized with advantage. In the first place, it is laid down that a moral obligation rests upon every attendant to respect the confidence of his patient, and that without her consent he is not justified in disclosing information obtained in the course of his professional attendance. Moreover, on becoming convinced that criminal abortion has been practised on his patient he should urge her, especially if she is likely to die, to make a statement which may be taken as evidence against the operator—provided always that doing so will not imperil her own chances of recovery. If she refuses there is no legal obligation on him to take action—"so the college is advised." From which expression it is to be presumed the question has been submitted to distinguished counsel for opinion. The medical man should, however, continue to attend his patient.

The new resolution of the college is to the effect that a practitioner before taking any action which

may lead to legal proceedings would be wise to avail himself of the best advice, both medical and legal, within his reach. He would thus insure that the patient's statement would be of value as legal evidence, and also safeguard his own interests, since in the present state of our law he cannot be certain of protection against subsequent litigation. If the patient should die, the certificate of the cause of death should be refused and the case referred to the coroner.

These conclusions have been formulated as resolutions and adopted by the college, which issues concurrently the statement that it has "been advised" on this matter—no doubt by leaders of the legal faculty: (1) That the medical practitioner is under no obligation either to urge the patient to make a statement, or, if she refuses to do so, to take any further action. (2) That when a patient who is seriously ill consents to give evidence, her statement may be taken in one of the following ways: (a) A magistrate may visit her to receive her deposition on oath. If possible, facilities for being present should be given to the accused person or his representative. (b) If attendance of the magistrate cannot be secured, she may make a statutory declaration before a commissioner for oaths, who can be asked to visit her for the purpose. (c) Should the patient be firmly convinced that she is dying, only in such circumstances, she may make a dying declaration, and this may be made to the practitioner or any other person, and need not be signed or witnessed, though it is desirable both should be done.

A mothercraft and child welfare exhibition has been held here. Model rooms, nurseries, beds, toys, gardens, and many ingenious devices for promoting the health of infants and children were shown. Articles of diet and clothing to be avoided, and others to be recommended, were also exhibited. They illustrated the great improvements in mothercraft which have taken place in the last few years. The fly exhibit demonstrated how flies grow and multiply, carry disease, and may be got rid of.

2. Lobar Pneumonia.—F. T. Lord outlines the following as measures which may be expected to diminish the incidence of pneumonia: (1) Education of the public concerning the manner in which respiratory infections take place and the means of avoiding them. (3) Closer supervision of the acute respiratory infections, such as ordinary "colds," so-called influenza, bronchitis and sore throats, and isolation of the more severe types of these simpler infections when possible. (3) Closer supervision of patients with pneumonia by making pneumonia a reportable disease and by the isolation of patients with pneumonia. (4) Avoidance of overcrowding and the regulation of housing conditions. (5) The diminution of dust in cities. (6) Immunization of those exposed in times of epidemics.

5. Preventable Heart Disease.—R. I. Lee states that while it is true that certain infections like the tonsillitis-rheumatic fever symptom-complex group and syphilis are particularly associated with cardiac disease, yet logically every infection may be regarded as a possible carrier of damage to the heart. There does not seem to be adequate appreciation of the possible sequelæ of infections, particularly rheumatic fever. Continued supervision after infections is important in order that an early endocarditis may be detected and the resulting damage be minimized. At present the development of medical inspection and supervision of school children seems the next step. The prevention of infections is an enormous problem, but must be faced. It is possible to control better scarlet fever and syphilis. It is possible to make milk supply reasonably safe, and it is possible to remove diseased tonsils. It is the fashion now to remove tonsils in as many school children as possible. It is still an open question as to the desirability of removing moderately large tonsils in the absence of history or evidence of disease processes in or connected with the tonsils. While further legislation may be of assistance, the true solution of this problem can be found in the proper appreciation by the public and the medical profession of the danger of all acute infections. The avoidance of infection and the prevention of its spread is largely a matter of personal hygiene.

1. Total Transverse Lesions of the Spinal Cord.—J. H. Lloyd notes that Bastian, in 1890, first pointed out the effects of total transverse lesions of the spinal cord in man. In these lesions there is complete flaccid paralysis, with absence of the tendon jerks, and complete anesthesia; also paralysis of the sphincters, and wasting and degeneration of the muscles. This syndrome is so widely at variance with preconceived ideas about the physiology and pathology of the spinal cord, that it has always presented something of a problem in neurology. Charcot and his school had taught that an interrupting lesion in the pyramidal tracts, causing lateral sclerosis, was always followed by a spastic paralysis, with increased tendon reflexes, below the seat of the lesion; and this is a common observation in the case of such a lesion. The explanation offered by Charcot was that an inhibitory influence of the cerebrum was cut off, and that in consequence the lower centres in the cord overacted; and this overaction was intensified by a constant inflow of sensory stimuli. The reflex arc, as it were, was liberated from the governing control of the cerebrum, and a spastic or hypertonic paralysis resulted, with exaggerated reflexes. It was taught, moreover, that the nutrition of the paralyzed muscles was not affected, since the trophic function of the multipolar cells in the anterior horns of the spinal gray matter was not interfered with, much less abolished. Such a descending lateral sclerosis, with hypertonus, spastic paralysis, and increased tendon jerks, is seen in old hemiplegias and in many lesions of the spinal cord. In the lower animals it seems that the spinal cord preserves more of an autonomy than it does in the higher vertebrates. Thus the decapitated frog and the decapitated snake present

very lively coordinated movements, which must be entirely localized in the spinal cord. But in man a total transverse lesion serves practically to abolish all functions in the cord below the level of the lesion, showing that in man the spinal cord preserves little if any autonomy, but depends for its functioning upon its connection with the higher cerebral centres. Among these functions to be abolished are not only the deep reflexes, but also the muscular nutrition. The author believes that this may be the whole explanation of the phenomena seen in cases of total transverse lesion. In the higher vertebrates evolution has gone on to the development more and more of the pallium or cerebral hemispheres, which have gradually assumed, in some obscure physiological way, supreme control over the lower or cord centres. When these latter are completely cut off, they languish and finally cease to function.

2. **Renal Tuberculosis.**—E. F. Kilbane points out that many cases of tuberculous kidneys exist without causing symptoms. When symptoms do occur, they may be referred to organs other than the kidneys. There is no relationship between the severity or duration of the symptoms and the extent of the kidney involvement. Every case of silent renal tuberculosis may at any time become active or the source of infection of other structures. Nephrectomy, therefore, is the logical treatment for uncomplicated unilateral cases as soon as a diagnosis is possible.

6. **General Faradization in Treatment of Obesity.**—By H. F. Wolf. (See MEDICAL RECORD, Vol. 87, page 501.)

8. **Hernia in the Chronic Insane.**—J. A. Jackson states that from five to six per cent. of the male chronic insane in the Philadelphia Hospital for the Insane have hernia, usually inguinal. Hernia rarely develops after admission to the hospital. It does not develop in the insane during excitement or as a result of confinement and physical degeneration. The question arises: Is hernia due to the muscles suddenly acting directly opposite to each other, whereby the inguinal canal is weakened? Palliative treatment consists of careful examination by physicians and trained attendants. Trusses may be used in a selected class of cases; the absence of trusses, however, does not aggravate the condition nor increase the tendency to strangulation. Operations are not necessary, except in the case of strangulation or for physical comfort. Strangulation is an infrequent complication.

2. **Prognosis of Congenital Clubfoot.**—E. W. Fiske concludes that there are three factors in the prognosis of congenital clubfoot: the age and rigidity of the foot, neglect, and the method of treatment employed. Of these, the last is the one controllable and predicable factor. Other things being equal, favorable prognosis is proportionate to the flexibility of the foot, which is usually in indirect proportion to the age of the child. Absolute overcorrection of the foot and unremitting attention to the maintenance of this position until the structures have become permanently readjusted, are essential. The deformity being shared by all the structures of the foot, that treatment only which is not localized in its application is productive of uniformly satisfactory results. The destruction of any tissues prevents the restoration of natural shape, strength, and balance of the foot, and is prejudicial to the return of normal function. The nonoperative or so-called manipulative treatment of clubfoot avoids these errors in treatment, and takes advantage of the plasticity and growths of the foot. By the manipulative method, overcorrection of the foot is rapidly and thoroughly effected, and relapse is seldom seen. By the manupulative method, almost twice as many cases show ultimate satisfactory results as do those with operation. The manipulated cases are easy and practical of management, and overconfidence and carelessness are often prevented by the nature of the treatment. Although the cases are rarely so severe, the prognosis for perfect result in calcaneovalgus is not so good as in equinovarus, largely because of delay in diagnosis and failure to maintain overcorrection.

8. **Potassium Iodide and the Luetin Reaction.**—J. W. Sherrick finds that a positive pustular or nodular luetin reaction can be obtained in 99 per cent. of all cases irrespective of the presence of syphilis, by the administration of potassium iodide, either simultaneously, or shortly before or after the intradermal test. Other substances, such as agar and starch, when injected intradermally, will give a similar reaction when potassium iodide is administered, but with these substances the potassium iodide must be administered within a shorter time than is the case with the luetin. Other drugs containing iodine have a similar influence on the luetin reaction.

9. **Craniometry in Diseases of Children.**—By G. H. Clark. (See MEDICAL RECORD, July 3, 1915, page 36.)

11. **Carbon Dioxide Tension in Alveolar Air.**—P. Roth states that acidosis is of frequent occurrence in a relatively large number of diseases. It is detrimental in all degrees of intensity; therefore should be looked for, its degree estimated, and efforts to control or combat it should begin early. The estimation of the carbon dioxide tension in alveolar air is as yet the simplest, quickest, and most reliable practical method to determine the degree of acidosis. Simpler methods and apparatus are needed. The author has devised a simple method of collecting samples of alveolar air during unconsciousness as well as in all other conditions.

2. **A New Antiseptic Mixture.** — P. Fildes, L. W. Rajchman, and G. L. Cheatle employ the following formula: Bichloride of mercury (cryst.), 1 gram; 80 per cent. alcohol (industrial), 100 c.c. Malachite-green (pure), 10 gram; 80 per cent. alcohol (industrial), 100 c.c. The two solutions are kept separate in bulk and mixed for use in equal parts. It is found that if the two parts are mixed together and kept for several days a compound of mercury and malachite-green crystallizes out of solution. The malachite-green must be pure, since most of the samples upon the market contain over 50 per cent. of adulterants. These solutions are to be applied in a spray and the treatment must be thorough, comprising the whole wound and a wide area of the surrounding skin. A superficial sprinkling over a wound is of no value. There is a tendency to apply the mixture insufficiently owing to the smarting which results from the alcohol basis in the same way as with iodine. This smarting, however, occurs only during the first three or four days of the treatment of a fresh wound, and though sometimes unpleasant does not persist for longer than 1½ minutes. If the mixture is applied with a good spray held as far as possible from the wound and if the wound is vigorously fanned this disadvantage may be reduced to a minimum. After the first three or four days the application is painless. Care must be taken that the alcohol has entirely evaporated from the skin before the dressings are applied, otherwise blisters may result. This is particularly important when fomentations are superimposed upon the mixture; in fact, the stronger formula should not be used together with fomentations.

7. Cheap Absorbent Dressings for the Wounded. C. W. Cathcart.

1. **Spiritus Ætheris Nitrosi.**—C. R. Marshall and Elizabeth Gilchrist find that the commonly accepted view that ethyl nitrite is the active ingredient of this mixture is correct. Although the other ingredients play a part in its action this is a subordinate one, and is of little practical importance. The rapid loss of ethyl nitrite which follows the addition of water strongly suggests that to obtain the best effects it is necessary to prescribe sweet spirit of niter as such and to dilute it just before administration.

4. **Antiseptic Action of Hypochlorous Acid.**—J. L. Smith, A. M. Drennan, T. Rettie, and W. Campbell report the results of their experiments which apparently confirm the conclusion already arrived at by various investigators that hypochlorous acid is the most powerful antiseptic known. It can be used either as a gas or as a solution. The advantage of using the gas is that it will penetrate and will act at a distance. Both the gas and the solution, while extremely potent against organisms and their spores, cause little or no harm to the tissues. The effect of this antiseptic is purely local; the decomposition products are devoid of toxicity, and there is therefore no danger to be apprehended from absorption. A flow of lymph is induced from the wound as part of the reaction of the tissues. Fetor is rapidly eliminated. If pain and irritation occur they can be easily controlled by reducing the concentration of the antiseptic. The practical advantages of this antiseptic for field use are: It can be used as a dry powder and therefore obviates the difficulty of procuring water. It can be introduced into the gauze pad of the first field dressing. Where water is available the same powder can be made up as a lotion for general use. The constituents of the powder are inexpensive and easily procured; and the preparation of the antiseptic is extremely simple.

6. **Diagnosis of Typhoid Fever in Inoculated Subjects.**—G. D. Dawson concludes that a positive reaction with the *B. enteritidis* 7160 is due to something more than previous antityphoid inoculation, and hesitation in diagnosing typhoid (or paratyphoid) infection should be occasioned only by the necessity of excluding infection with the *B. enteritidis* itself. The symptoms associated with *B. enteritidis* infection are, however, generally clear enough to make the distinction easy. A single negative test with the *B. enteritidis* 7160 does not exclude a diagnosis of typhoid fever, though, if obtained late in the course of an illness, it would constitute good evidence against typhoid infection. Repeated negative tests are much more conclusive, and should be of value in deciding the nature of doubtful cases. The time required, however, is a hindrance to rapid diagnosis, which is absent in the case of a positive reaction.

Berliner klinische Wochenschrift.

June 21, 1915.

Epidemiology of Typhus Fever.—Jürgens calls attention to the fact that for decades there have been no epidemics of typhus on German soil, but that now the Russian prison camps are the seat of true epidemics. Typhus first broke out in November as an influenza-like affection. Case after case developed and the symptoms raised suspicion of typhus. Soon it became apparent that no influenza had existed. The epidemic had developed with singular suddenness and ravaged the entire camp, despite isolation and other preventive measures. As a rule in epidemics there is some irregularity in spread—a breaking out in batches—but in this one the course of diffusion was like an endless chain. There was no surcease as long as a healthy man remained in the camp. This peculiarity, always remarked in typhus, we now know to be due to the rôle of the louse in the transmission of the disease. The epidemic was dealt with by annihilating the vermin, and as soon as this had been accomplished the disease was no longer transmissible. The sound mingled with the convalescent with impunity. But carriers doubtless exist, and the lice can cause new cases should these subjects again become lousy. Another factor must, however, be reckoned with, to wit: the stage of development or degree of virulence of the actual parasite as it circulates in the carrier's blood or louse's body. It is certain that some of the German victims of the disease showed no evidence of lousiness when first seen, but this can only mean that the lice who attacked them had no opportunity of settling upon their clothing by reason of their cleanly habits. Over and above all, however, are the peculiar laws of contagion which are evident in all epidemics of contagious disease—the so-called *genus epidemicus* which makes one epidemic trivial and another malignant.

Cumulative Appearance of Infectious Parapneumonic Streptococcus Empyema.—Tykociner mentions cumulation of ordinary pneumonia in the wet, cold winter, and early spring months in those who are exposed much to the weather, and who get wet through again and again without opportunity of changing their clothing.

Other cumulation can occur, as in a series of cases seen by the author, five all told, in which empyema was a complication (four cases) or a sequel (one case). Thoracentesis with rib resection was performed in five cases. Two of the six patients died of the disease. Two patients appeared to have contracted their disease from two others. In three cases the empyema pus contained streptococci in pure culture and in the three others the same organism was associated with pneumococci or other germs. It seemed certain, however, that the streptococcus was throughout the virtual pathogenic. It is believed in some quarters the *Streptococcus pneumonia* is contagious. The author's patients presented much the same symptoms. They were seized with chills, stitch in the side and cough, and at once took to their beds. Rusty sputum and dyspnea were present. Evidences of empyema appeared between the third and sixth day in the five parapneumonic cases. The complication prevented the development of a crisis. A study of the cases and certain remarks by the author show that in one "parapneumonic" case the empyema was primary, and that no pneumonia was found at autopsy.

Etiology of Eclampsia.—Schröder gives a general account of the various doctrines concerning the nature of eclampsia. That it is a poisoning is beyond all doubt. The nature of the toxic agent is obscure but authors have had little doubt that its source is either the fetus or placenta, and of recent years the latter has superseded the former as the probable seat of origin. Evidence to this effect has been cumulative. Placental protein is heterologous to maternal blood, and eclampsia may even be regarded as an anaphylactic shock. But the placental theory cannot explain post-partum or self-limited eclampsia. The author therefore chooses to believe that the toxic substance is a product of intermediate maternal metabolism, either a high molecular clearage product or a low molecular derivative near as low in clearage as the amines. These products can cause respectively actual convulsions and a spasmophilic state.

Münchener medizinische Wochenschrift.

June 22, 1915.

The Fly Plague.—Volkmann refers to the plague of flies at the front, due to the great amount of putrefying material (cadavers, perishable food, dejecta, etc.). Bodies should be buried deep, at the greatest possible distance from the water supply. If they cannot be buried at once they should be strewn with chloride of lime. Provision for all these measures had been made in advance but there has been some lack of enforcement. Incineration is of course ideal for the disposition of putrescible material. All food should be screened to prevent fly blowing and pollution with excrement. In doubtful cases food should be scraped, washed, or cooked to destroy contaminating substances. Disposal of feces is the most difficult problem in connection with flies. Garbage can be quickly burned, as may also old wound dressings, but these duties are often neglected. Feces can at most be buried, as such extensive use of disinfectants is impracticable. In field hospitals the helpless patients suffer much from flies. The best preventive is to hang strips of fly paper from the ceilings, etc., and change them often. Fly traps are of less value and expensive. Screens for windows are said to be out of the question as these are in such demand for kitchens and pantries. However, gauze curtains hung over windows furnish a fair substitute. In a second article Kirschner objects to sticky fly paper as unappetizing and even costly. Instead he would fill soup plates with beer which contains a certain amount of arsenic in solution. The flies feed on the beer with avidity. The plates should be marked "poison."

Effects of Heat Stroke.—Bittorf states some experiences of the previous summer. Some soldiers died at the front or soon after admission as a result of heat while others reached the hospital still prostrated, but on the road to partial recovery. A number of these had not recovered as late as the following spring. Most patients when admitted complained of headache and prostration. Sooner or later hysterical convulsions developed. Epilepsy could be excluded. In individual cases there were seen tachycardia, tachypnea, speech disorders, disturbances of sensation, tetany. Without an exception hysterical manifestations of some sort followed the insolation. Predisposition was quite wanting. It was clear that overheating the cerebral cortex is able to cause hysteria in any subject. While the prognosis on the whole is unfavorable for complete recovery all the soldiers returned to garrison duty at least.

Progress in the Domain of Pulmonary Diseases.—Blümel notes favorable reports of treatment of bronchitis and bronchiolitis, also bronchopneumonia in young children and nurslings with hot baths at 40°-40.5° C. duration ten minutes. At first they are given three or four daily, reduced later to one or two daily. The favorable influence on fever, respiration, and expectoration is marked. In bronchitis of adults hydrastic preparations, suprarenin and benzoate of sodium and caffein are being used. Iodides are useful in practically all forms of bronchitis, especially some of the recent organic combinations of iodine. Broncial asthma may be controlled readily by atropin-adrenalin injections. A proprietary combination of suprarenin and hypophysin is also recommended. Artificial pneumothorax may cause but little improvement in old bronchiectases. For the prophylaxis of this condition it is well to treat pleurisies and pneumonias until resolution is complete. Hot air inhalations and respiratory gymnastics benefit both asthma and bronchiectasis by keeping the cavities and tubes empty and ventilated. When the amount of sputum is very large a thirst cure may be tested. Freund's operation for emphysema pulmonum seems to have little vogue at present; the ultimate results are not encouraging.

Deutsche medizinische Wochenschrift.

June 17, 1915.

Luetic Gastric Sclerosis.—Mühlmann reports a case of this very rare condition, as follows: A woman aged 27, previously healthy, had contracted syphilis five years before. The disease showed a marked tendency to relapse. One year before consultation she began to suffer with her stomach. With appetite unimpaired she complained of pressure and pain and vomited when food was taken beyond a fixed limit. She was constantly hungry and was nibbling all the time. She could not ingest half a pint of milk or its equivalent in bulk without promptly rejecting it, and soon became emaciated and anemic. The stomach contents after a test meal showed absence of free HCl, presence of lactic acid. The *x*-ray showed a small stomach, no peristalsis, pylorus small and constantly open, chyme passing through. The diagnosis of luetic sclerosis was made without reservation. The case being a surgical one, gastroenterostomy was promptly performed. The stomach was found to be small, with thickened walls. Salvarsan and mercurial inunctions were given. The improvement became marked in all respects, although the Wassermann reaction remained positive. The *x*-ray showed no change in form in the stomach. The gastroenterostomy functioned well. The lower esopha-

gus showed a dilatation. Study of a microscopic section showed absence of epithelium. The esophageal dilatation and lactic acid pointed to retention despite the constant passage of chyme through the rigid pylorus and later through the anastomosis. Three other carefully studied cases are on record and these show a marked agreement with the author's observation. It is of course very difficult to prove that the sclerosis was due directly to syphilis, in the absence of spirochete finds *in loco*. The treatment, despite its prompt benefit, could not restore the gastric structure and functions. The inflammatory process in the gastric wall, however, must have been arrested.

The Coolidge Tube.—Schmidt obtained one of these American tubes before they had been placed on the German market and reports concerning it as follows: It can readily be made to supply rays of any degree of hardness from 1 to 12 Wehnelt writes, and this degree will readily persist for an indefinite period. Therefore, this tube takes precedence over all others for diagnostic purposes. It can also sustain a larger charge of soft and medium rays than any other tube without any alterations in hardness.

Mortality of Noncombatants in Berlin from August, 1914, to January, 1915.—Gottstein finds that cancer mortality was unchanged, so that the emotional, dietetic, and other alleged factors in the production of malignancy are not in evidence. There has been an increased mortality from tuberculosis, and the acute, infectious diseases show even a decline, but this can have no connection with the war. There is also a falling off in nursling mortality. Of interest is the decline in suicide mortality in both sexes. On the other hand, deaths from cardiovascular disease are increased. This is no doubt due directly to the war, but the age of the decedents must be taken into account and worry, grief, etc., have acted rather upon the general vitality than upon the circulatory system.

Deutsche medizinische Wochenschrift.

June 24, 1915.

Clinical Experiences in a Typhoid Hospital in East Prussia.—Jacob has recently treated 300 cases of army typhoid. The cases were frequently severe and complications and relapses were common at the outset. At a later period the disease pursued a much milder course. There next followed a period in which cardiac weakness and pneumonia abounded. Another benign period then ensued. These vagaries could be brought into relationship with typhoid immunization, as will be seen later. The effects of the Widal diagnosis have been largely invalided by the antityphoid inoculation, and the diazo is now much more valuable. Of still greater value is the bile test, *i.e.* inoculation of bile culture media with a few cubic centimeters of typhoid blood. The results are 90 to 95 per cent. positive. Research for bacilli in urine and feces is not very satisfactory. The presence of hypoleucocytosis should not be undervalued. Disappearance of eosinophiles during the critical period and their reappearance later in the disease also possess real diagnostic and prognostic value. Of complications deafness from toxic labyrinth disease and meningism were common. Delirium was not attended by war memories; as a rule patients fancied themselves at home. Both specific and nonspecific boils and abscesses developed, and the diseased seemed able to mobilize an ordinary furunculosis. In certain cases latent tuberculosis was activated. In from 20 to 30 per cent. of fatalities pneumonia had developed, while as many more died of exhaustion, due not a little to defective nourishment in the early course of the disease. There was no parallelism between severe enteric lesions and a grave type of infection. In regard to protective inoculation this has been carried out in other diseases besides typhoid—smallpox and cholera. To prevent confusion ordinary vaccination had been practised as usual on one of the arms and immunization against typhoid and cholera on one or the other side of the chest. The soldiers were almost always ignorant in regard to which disease they had been immunized against. To form a means of discrimination the author ordered typhoid inoculation to be practised three times between the left nipple and collar bone, and cholera inoculation twice in the corresponding area on the right side. The soldiers were also carefully informed as to what the inoculations represented. In the author's series of typhoid inoculations the disease in the great majority was already developing and his figures should not be grouped with true prophylactic immunizations. The author was pleased with his results because the disease ran a mild course and relapses did not develop. To obtain results of this sort, however, inoculation must be practised at a relatively early period in the disease. When the latter has fully developed its course is not influenced thereby.

Occupations for Soldiers Blinded in the War.—Krückmann enumerates three special classes of hand work in addition to others long practiced. These comprise rope making, brush making, and basket and chair weaving. Three years' time are required in an average for apprenticeship. For these three crafts there is an abundance of raw material in peace times, and evidently the author has in mind only a state of affairs to come after the war is over. For rope making hemp comes from Russia and Italy, jute from India, aloe from the Pacific Islands. Bristles, etc., for brushes come from Russia, India, and China. In regard to basket work some materials are of domestic origin, but bamboo, rattan, varnish, etc., must come from abroad. There is a museum in Brussels which has exhibits of all raw materials and the goods which are or may be made from them. Ropemaking is not very well suited for the blind and has been repeatedly given up in institutions. Brush and broom making is a success for some of the blind, while basket work appeals most to the larger number. Massage by the blind has not been much of a success in Germany. Music holds out some promise, as the blind are fond of it, and often develop great talent in the use of various instruments. The fingers of the ex-warriors are, however, rather too stiff for mastering instruments in the absence of previous training. The author discusses other possibilities for rendering the blind self-supporting.

Abscess of Liver Due to a Streptothrix.—A. Bloomfield and S. Bayne-Jones report the case of a man aged thirty-two years who presented a chronic low-grade pulmonary streptothricosis from which was isolated in pure culture the organism found in the sputum. The points of interest are the fulminating character of the hepatic involvement during the course of a practically latent pulmonary disease.—*Bulletin of the Johns Hopkins Hospital.*

Secretion of Cerebrospinal Fluid.—C. H. Frazier and M. M. Peet note that the intravenous injection of diiodotryosine has an inhibitory influence on the rate of secretion of the choroid plexus. Iodothyrine in solution, injected intravenously, has little influence on the rate of cerebrospinal fluid secretion when given in small amounts (0.05 gram). In amount of 0.03 gram and 0.5 gram there is some inhibition of the rate of choroid plexus secretion but not as marked as that produced by diiodotyrosine or saline extracts of fresh thyroid.—*American Journal of Physiology.*

Insurance Medicine.

Life Saving As a Function of Life Insurance.—In a broad and general sense, can human life be saved? Or is the human race still measurably below a perfect adjustment to environment? Dr. Eugene L. Fisk, director of hygiene, Life Extension Institute, New York, answers his own questions by saying that a perfect adjustment of the race to environment has not been reached, but that our civilization has developed powerful resources for the upbuilding of resistance to disease and for the prolongation of human life, which have been used for systematic and intensive work among policyholders in a number of important companies. Life saving has actually become a function of life insurance.

The most striking instance of a smashing of the death rate by an adjustment of the environment to the individual is shown by the work of Gorgas in the Canal Zone, where diseases that had been regarded as necessary afflictions, or "acts of God," were practically eliminated and an annual death rate of 48,000 hammered down in five years to 21,000. "Public health is a purchasable commodity." This general conquest of pestilential and communicable diseases has lowered the death rate in all civilized communities during the past thirty years and life insurance companies have shared with the general public in these benefits. They can afford to aid in this warfare by educating their policyholders in their duties to the State and by carrying to them in the most authoritative and effective way a knowledge of community and household hygiene.

In 1903 Mr. John K. Gore called attention to the increasing mortality from the degenerative affections, as shown in the records of the registration cities in the United States; also to the improvement in the death rate among young lives and the increase in the death rate among the elderly. Subsequently the research carried on by Dr. Fisk and Mr. E. E. Rittenhouse developed an amount of evidence showing that in the United States registration area as a whole and in separate States and registration cities a fall in the death rate from typhoid fever, tuberculosis, and other communicable diseases has accompanied a decline in the death rate under forty years, similar in degree to that exhibited in England and Wales. Unlike the British experience, there was a pronounced rise in the death rate at the later age periods, paralleled by a very heavy increase in the death rate from diseases of the heart, blood-vessels, and kidneys. The British statistics for a given period showed that the mortality from these diseases in the aggregate had remained stationary, although lately showing a downward trend consistent with the improved mortality at the older ages. In the recent medico-actuarial investigation of the experience of forty-three companies, a similar trend is exhibited—a pronounced improvement among the young entrants, 15 per cent. for ages under forty, this improvement rapidly diminishing and changing into an increase of 2 per cent., after age sixty. Dr. Fisk's own investigations show a fall in the death rate during the past thirty years among entrants under twenty-five of 30 per cent. and an increase in the mortality after sixty.

What is the remedy for this life waste at middle age? In factories and mills the machinery is constantly examined by men employed for that express purpose. Is it too much, then, to inspect once a year the marvelously complex human machine with its almost infinite capacity for going wrong? We should thoroughly examine the human body once a year. It is not enough to keep people out of sick beds, they must be lead up to higher planes of average health and physical efficiency. This is properly a function of life insurance because (1) a life insurance company has a direct business interest in reducing mortality, if the mortality saving will cover the cost of doing the work; (2) a life insurance company has available the channels through which it can readily and effectively reach a vast body of people (there are 6,000,000 policyholders in the United States, each of these with his greater or lesser zone of influence); and (3) because the successful performance of this function would just about double the value and meaning of life insurance as a social institution.

In 1909 the Provident Savings Life Assurance Company extended this privilege of yearly examination to its policyholders. This was continued later by the Postal Life. Approximately 2,500 people were examined, 1,000 of whom were found sufficiently impaired to require medical treatment or advice. The average age of the impaired risks was fifty-one, and the average duration of the policies twelve years, while the actual mortality as compared to the expected by the American table was only 93 per cent. No matter how favorable the mortality may be in any particular company, the offer of this privilege of health examinations will draw a certain number of seriously impaired sub-standard and border-line risks, among whom the possibility of saving is quite as great as that above noted.

"Laugh and Grow Fat" is not good advice for the man or woman who is inclined to be heavy. Mr. Arthur Hunter, Chairman of the Central Bureau of the Medico-Actuarial Mortality Investigation, and Actuary of the New York Life Insurance Company, states that there is no doubt that marked overweight has a material effect in decreasing length of life, especially at the middle and older ages. Among men 40 lb. above the average weight the lifetime of those who entered the companies at forty-five was about 4 years less than that of men of normal weight. The public should understand that marked overweight is a serious handicap to length of life. Diabetes, Bright's disease, heart disease, and apoplexy cause a large proportion of the deaths among overweights. While the over-eater is not such a bad social influence as the excessive drinker, the former is also shortening his life by lack of moderation. Insurance companies will be glad to give to the public such information needed to overcome incorrect living, and methods by which improvements may be made.—Association of Life Insurance Presidents, New York, December, 1914.

Accident Insurance and Drowning.—A shock and fainting spell produced by entering into a swimming pool, which results in drowning, are held in Clark v. Iowa State Traveling Men's Association (Iowa), 42 L.R.A. (N.S.) 631, not to relieve an accident insurance company from liability on its policy for the death, on the theory that the death resulted partially or indirectly from "disease or bodily infirmity," within the meaning of an exemption clause in the policy.

Book Reviews.

URINARY ANALYSIS AND DIAGNOSIS by Microscopical and Chemical Examination. By LOUIS HEITZMANN, M.D. Third Revised and Enlarged Edition. One volume, 8vo, illustrated by original wood engravings. New York: William Wood & Company, 1915.

HEITZMANN'S book is so well known as hardly to require a very detailed review. Three editions are the best proof of the value of a book. The first part, dealing with chemical examinations, aims to include all the simpler methods and tests, omitting the more complicated tests, but giving those of most usefulness generally. The second part, dealing with microscopical examination, is more full, and the author emphasizes his belief that by careful, high-power study of urinary sediment correct diagnosis is usually possible; indeed, that a very accurate localized diagnosis can usually be made. The third part contains a large number of illustrations, nearly all original drawings by the author, which cannot fail to be of the greatest assistance to anyone following these methods. If any criticism should be made, it would be that the book is a little too brief in the chemical division, as compared with the microscopical sections.

All who are concerned with the making of urinary analyses can hardly fail to find this book of the very greatest assistance. It is well printed and bound. While some of the illustrations might perhaps be criticised as too graphic, or crude, yet their illustrative value is not thereby impaired; indeed it may even be the greater on that account.

THE INTERNATIONAL MEDICAL ANNUAL. A Year Book of Treatment and Practitioner's Index. Contributors: E. WYLLYS ANDREWS, A.M., M.D.; SIR CHAS. BENT BALL, Bart., M.D., F.R.C.S.I.; JOSEPH G. BLUMFELD, B.A., M.D.; FRANCIS D. BOYD, C.M.G., M.D., F.R.C.P.; FRANCIS J. CHARTERIS, M.B., B.Ch.; G. LENTHAL CHEATLE, C.V.O., C.B., F.R.C.S.; JOHN D. COMRIE, B.A., M.D.; CAREY F. COOMBS, M.D., M.R.C.P.; JOHN S. FRASER, M.B., Ch.B., F.R.C.S.; HERBERT FRENCH, M.A., M.D., F.R.C.P.; BRYDEN GLENDENNING, M.S., M.B., F.R.C.S.; EDWARD W. GOODALL, M.D., B.S.; FRANCIS W. GOYDER, B.A., M.B., F.R.C.S.; COL. LOUIS A. LA GARDE, M.D., United States Army Medical Corps (retired); ERNEST W. HEY GROVES, M.D., M.S., F.R.C.S.; OSKAR C. GRUNER, M.D.; C. THURSTAN HALLAND, M.R.C.S., L.R.C.P.; ROBERT HUTCHISON, M.D., F.R.C.P.; FREDERICK LANGMEAD, M.D., F.R.C.P.; E. G. GRAHAM LITTLE, M.D., F.R.C.P.; CHARLES FRED. MARSHALL, M.D., F.R.C.S.; KEITH W. MONSARRAT, M.B., F.R.C.S.; JOS. J. PERKINS, M.A., M.B., F.R.C.P.; BEDFORD PIERCE, M.D., F.R.C.P.; JOSEPH PRIESTLEY, B.A., M.D., D.P.H.; SIR LEONARD ROGERS, Lt.-Col., I.M.S., M.D., F.R.C.S., Calcutta; A. RENDLE SHORT, M.D., B.S., F.R.C.S.; PURVES STEWART, M.A., M.D., F.R.C.P.; A. HUGH THOMPSON, M.A., M.D.; J. W. THOMSON WALKER, F.R.C.S.; A. GASCOIGNE WILDEY, Dept. Surg., Gen. R.N.; JOHN H. YEARSLEY, F.R.C.S. 1915. Thirty-third Year. Price $4.00 net. New York: William Wood & Company, 1915.

THERE are many good things in this volume which epitomizes the contributions made to medical science during the past year. Part I comprises a dictionary of materia medica and therapeutics and includes a description of the new British Pharmacopœia and an illustrated section on radio- and electrotherapeutics. Part II forms the main body of the work, consisting of a review of medical and surgical progress for 1914, together with a brief synopsis of treatment recommended during recent years. It opens with a general review, after which follow in alphabetical order short articles on subjects dealing with every phase of medical treatment. Among these may be mentioned those on abdominal incisions and injuries, abdominal pain in children, alimentary toxemia, amebiasis, anesthetics, arterial pressure, diseases of the bladder, pathology and serology of the blood, brain surgery, infantile diarrhea, epilepsy, fractures, heart disease, infant feeding, labor, diseases of the larynx (including a detailed description with full-page plates of suspension laryngoscopy), surgery of the esophagus, paralytic deformities, pyelography, rheumatoid arthritis, spinal cord surgery, tobacco poisoning, etc. Part III includes timely and interesting articles on modern naval and military surgery. It also contains an important contribution on antiseptics in war and the method of their application. In this article G. Lenthal Cheatle reports apparently for the first time the advantages of the use of combined solutions of bichloride of mercury and malachite green. One of the admirable features of the present issue of the *Medical Annual* is the new and more prominent type. There are a large number of illustrations, including 71 full page plates, many of which are colored. In briefly characterizing this volume one may state it represents a practical digest of a year's contributions to medical science, particular attention being paid to methods of treatment.

INFECTION AND IMMUNITY. A Textbook of Immunology and Serology, for Students and Practitioners. By CHARLES E. SIMON, B.A., M.D., Professor of Clinical Pathology and Experimental Medicine at the College of Physicians and Surgeons; Pathologist to the Union Protestant Infirmary and the Hospital for the Women of Maryland; Pathologist to the Mercy Hospital of Baltimore, Maryland. Third edition, revised and enlarged. Illustrated. Price, $3.25. Philadelphia and New York: Lea & Febiger, 1915.

A COMPARISON of this edition with the preceding shows that there has not been any notable increase in the amount of material, although the work is now given rank as a textbook instead of an introduction as formerly. One important innovation to be seen in the present volume is a full bibliography at the close of each chapter. The number of the chapters remains the same. Under immunological diagnosis the section on the Wassermann reaction has been almost completely rewritten, the subject of ferment reactions has been amplified, and there is a section on gonococcus reactions. The subject of anaphylaxis has received interesting additions, with especial reference to diphtheria and tetanus. It is further noted that Hodgkin's disease may prove to be amenable to vaccinotherapy.

The relatively small size of this work is evidently to make it acceptable as an elementary textbook and at the same time as a reference work for the general practitioner.

DIE TIERISCHEN PARASITEN DES MENSCHEN, die von ihnen hervorgerufenen Erkrankungen und ihre Heilung. Bearbeitet von Dr. MAX BRAUN, o.ö. Professor der Zoologie und vergl. Anatomie, Direktor des zoologischen Museums der Universität Königsberg i. Pr., Geh. Regierungsrat, und Dr. OTTO SEIFERT, a.o. Professor fur Rhino-Laryngologie, Vorstand der Poliklinik fur Nasen und Kehlkopfkranke der Universität Würzburg. I. Teil. NATURGESCHICHTE DER TIERISCHEN PARASITEN DES MENSCHEN. Von Dr. MAX BRAUN. Fünfte, vermehrte und verbesserte Auflage. Price Mk. 13. Würzburg: Verlag von Curt Kabitzsch. 1915.

SINCE the fourth edition of this work not only has the information concerning the life history of the animal parasites of man increased very largely, but their pathological significance has increased to a tremendous degree. Many of them have been identified as the causes of hitherto obscure diseases while in other instances they are the carriers of the actual causative organisms. In the European war the parasitic plague has become very important because of its prevalence, and the appearance of this edition is all the more timely on that account. This edition has been thoroughly revised and embodies the results of recent investigations. There is appended nearly one hundred pages of references to the literature of the subject. This work remains as it has been in the past, the best one on the subject.

THE CLINICS OF JOHN B. MURPHY, M.D., Vol. IV, No. 1, February, 1915. Octavo of 185 pages, 41 illustrations. Published Bi-monthly. Price per year: paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1915.

AMONG the subjects of especial interest in this number may be mentioned: The relation of cancer research to the clinical aspects of cancer; aneurysm of the brachial artery—aneurysmorrhaphy; division of the brachial plexus with suture of the divided nerve trunks; carbuncle of the arm, followed by septicemia, metastatic pleurisy, and death; and a discussion of the treatment of contracting cicatrices based upon a case of that nature affecting the index finger and thumb. About one-third of the book is taken up in the discussion of bone cases. Is it too much to hope that some future issue will contain no references to that division of surgery?

Society Reports.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, June 2, 1915.

THE PRESIDENT, DR. JAMES C. WILSON, IN THE CHAIR.

Rupture of Portal Vein Causing Intrahepatic Hematoma Simulating Rupture of a Hollow Viscus. — Dr. JOHN E. ROBERTS cited the case of a man who fell across a step in the street and struck the upper portion of the abdomen. He suffered great pain, was supposed to have a ruptured stomach or intestine, and was operated upon by the speaker a few weeks ago. The operation showed some free blood in the peritoneal cavity, blood in the gastrohepatic omentum and in the neighborhood of the pancreas. No bleeding point was found needing control ligature. The abdomen was therefore closed. Death, either from shock or ether poisoning, occurred just as the operation was completed. Post-mortem examination showed a large clot within the liver due to a rupture of one of the branches of the portal vein or of the portal vein itself just within the capsule of the liver.

Pelvic Horseshoe Kidney Simulating Perforative Appendicitis.—Dr. JOHN B. ROBERTS under this caption said that in February last operation was performed for what was supposed to be acute perforating appendicitis with adhesion of the ruptured appendix to the anterior belly wall. The operation was done hurriedly under antiseptic treatment of the skin, and mild appendicitis found without perforation. The swelling which led to the belief that perforation with anterior adhesion of the appendix had occurred was found to be a horseshoe kidney, the right portion of which lay immediately under the appendix across the spine near the sacral promontory. The right and left portions were connected by a fibrous band uniting the lower poles in this unusual position. These cases and others, Dr. Roberts said, demonstrated the value of the surgeon's doubting tendency before operating. Though no harm was done by operating, the diagnosis in both these cases was erroneous. In Dr. Robert's opinion surgeons needed a doubting mind, because the tendency to jump at conclusions and hastily operate sometimes subjected patients in abdominal, fracture, and other departments of surgery, to unnecessary risk. A few instances of this kind were given to show the truth of this statement.

Certain Syphilitic Affections of the Heart and Aorta. —Dr. A. M. ANDERS remarked that the advent of the Wassermann reaction had shown that the etiological role of syphilis in diseases of the cardiovascular system has been heretofore underestimated. While he would not say with recent investigators that syphilis was the principal factor in the production of heart disease, it could be assumed that rheumatism and syphilis headed the list as causes of organic injury to this organ. While the cardiac lesions caused by the *Spirocheta pallida* were usually considered as belonging to the tertian stage of syphilis, Grassman, Brooks, and other investigators had expressed the opinion that serious damage might occur as early as the fore part of the second stage. Aortic and cardiac syphilis might be the result of hereditary lues. The claim made by Landois, Citron, Hausmann, Sears, and others that lues might affect the heart alone, was interesting and important. In two infants who died, one at three months of inanition, the other at eight days of asphyxia, Warthin and Snyder found the *Spirocheta pallida* in the heart muscle, while neither histological lesions nor spirochetes were found elsewhere. Among the commonest cardiovascular conditions due to syphilis were myocarditis, aortic regurgitation, angina pectoris, and mesaortitis often resulting in aneurysm. Mesaortitis with or without coronary changes was commonly the primary complaint in cases in which, as frequently occurred, two or more of the above-named affections were found in association. That this condition was due in many cases to syphilis had been demonstrated both by post-mortem evidence and the results of carefully conducted therapeutic observations. The intimate connection between lues and aneurysm, well known to the older writers, had been emphasized by those of modern times. With Hausmann, Dr. Anders would caution the medical profession against regarding every cause of aneurysm, even in syphilitic subjects, as due to lues. Two differentiating etiological factors were that the root of the aorta was the usual seat of luetic aneurysms, which aneurysms were frequently multiple. Syphilis, it was said by the author, was now generally regarded as an essential factor in the causation of aortic incompetency, more particularly in cases developing before the forty-fifth year of life. As in aneurysm, a positive Wassermann reaction alone, unsupported by clinical evidence, did not warrant an assured diagnosis of lues although it rendered highly probable the existence of syphilis. On the other hand, it was to be remembered that aortic incompetency in a luetic subject might be due to other causes, especially if the lesion developed after middle life. Early involvement of the myocardium was not infrequent in the course of syphilis. Early recognition was difficult but important. The symptoms did not differ from those of myocarditis due to other infections and it had been shown that they disappeared promptly under energetic antisyphilitic treatment. Anginoid pains were occasionally present, and obliterative endarteritis implicating the coronaries and producing myocarditis might result in attacks of true angina pectoris. Although a positive or negative Wassermann test was not an absolute criterion it was noted that Brooks contended that it was better than the 70 per cent. of error based on the history or clinical findings alone. Of 270 cases of angina pectoris collected by Dr. Anders from the literature only 72 or 26.5 per cent. gave evidence of syphilis. This percentage was much too small, since in 250 of the cases no mention was made of a Wassermann test. The close association of syphilis and angina was amply confirmed by modern authorities. Dr. Anders' discussion of the treatment of cardiovascular syphilis was limited to prophylaxis. The incidence of cardiovascular disease he thought, without doubt, would be lessened by a more systematic and vigorous treatment of luetic infection in general. Physicians should feel the serious responsibility of the treatment of early syphilis in the wisest manner possible. This was further emphasized in the hazard of administering salvarsan or neosalvarsan in the severer forms of cardiovascular syphilis. It had been found that death occurring suddenly or after several days from the use of these agents, was commonly due to myocardial degeneration secondary to coronary lesions.

Dr. GEORGE W. NORRIS emphasized the statement of Dr. Anders that the discovery of the spirochetes and the knowledge of the Wassermann reaction rendered possible the recognition of a number of lesions as definitely syphilitic which in the past were barely suspected to be such. In this relation it was interesting to note that experimental medicine sometimes followed empirical medicine. It had long been known by practitioners that the iodides did good, as did also in a good many of these cases, small doses of mercurials. The way in which the iodides did good was not known because of lack of knowledge of the manner of their action, although it was assumed to be by the action of a proteolytic ferment upon granulomatous tissue. An interesting fact was the failure of the iodides unless combined with mercury. According to the modern treatment not only were both these drugs used, but frequently salvarsan in addition. In the recent increased attention given to syphilitic nephritis it was comforting to know that if mercury or salvarsan were given the nephritis was benefited rather than injury done to the kidneys by the otherwise irritating drugs. A point emphasized in literature was the frequency with which sudden death might occur in the case of syphilitic myocarditis in the young as well as the old. Among the symptoms of diagnostic value in syphilitic myocarditis were low blood pressure, mild angeoid attacks associated with dilatation of the left ventricle and as emphasized by Dr. Anders, cardiac irregularity followed by auricular fibrillation. In these cases it was well to remember that salvarsan should not be administered without due consideration. It was noted that salvarsan was not altogether an innocuous drug and did have a tendency to lower blood pressure. Another point of interest was that of syphilitic aoritis even in the young. It had been shown that a considerable percentage of newborn infants who died shortly after birth had spirochetic disease in their aorta. Gumma of the heart could be rarely diagnosticated during life because it often involved the silent regions of the heart; a presumptive diagnosis might, however, be made if the gumma involved the conducting system of the heart, in which was found a heart block. Cases of syphilis, Dr. Norris stated, were inadequately treated in the dispensaries. Some of the hospitals even refused, or did not like to treat syphilis in its early stages, and would not admit secondary lues to their wards. There seemed to

be a general attitude among the boards of managers in hospitals that it was the patients' own fault and that they therefore should stand the consequences. These same boards of managers, however, were perfectly willing to admit such patients when they returned with the disease at a practically incurable stage. More efficient and thorough treatment in dispensaries of syphilis was felt to be one of the crying needs of medical work of the present. After all, there was much truth in the dictum of Charcot that if syphilis and tuberculosis were known in all of their manifold manifestations such knowledge would include a large part of medicine.

Dr. JAMES TYSON said that in his experience as a young man in dispensary service it was their practice in the treatment of cases including rheumatoid affections to give first iodide of potassium. Failing with the iodide, mercurial bichloride was added and an astonishingly large number of cases were at once benefited upon the addition of the mercury. It would seem therefore that the new methods confirmed the old. Later observations and the demonstration of the syphilitic organisms were proving that which the therapeutic test so many years ago had shown. He had sometimes thought that, although this was a rough and ready method of treating symptoms, it might perhaps be adhered to a little more frequently than was done in modern times.

Dr. ANDERS, in closing, said he had seen several remarkable results in the alternate and also separate use of salvarsan and mercury in the treatment of syphilitic nephritis. On the other hand he cautioned that there must be certainty that syphilis was the real cause of the cardiovascular and renal conditions. He had recently seen very disastrous results from the use of mercury in a case of nephritis which had been misdiagnosed as being of syphilitic origin. The patient had died in a few days who otherwise might have lived for months or even for years. Mercury had its selective affinity for the kidneys and there was no other variety of nephritis than the syphilitic in which its use was justified. While it was true that since the discovery of the Wassermann reaction the true etiological importance of syphilis in many heart diseases had been in great part established, this could not be said of this test in relation to angina pectoris. He believed, however, that the close association of angina pectoris and syphilis would be established when the profession appreciated the importance of Wassermann tests in all cases of angina pectoris. During the early stages of syphilis he felt that the heart should be examined systematically. The neglect of this precaution was attended with untoward results he believed in many cases. Truly, with regard to cardiac involvement in the course of syphilis the words of John Locke were applicable: "Prevention is better than cure and far cheaper."

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Seventy-first Regular Meeting, Held May 7, 1915.

DR. A. A. SMITH IN THE CHAIR.

Observations on Sera.—Dr. WILLIAM H. PARK said that physicians rarely recognized the reasons which caused the different sera to be of unequal value and to be applied in different ways. The antitoxic sera were alike in that they could absolutely prevent infection and neutralize any required amount of toxin. The diphtheria antitoxin produced in an animal through the stimulation of the extracellular toxin produced by any diphtheria bacillus would neutralize the toxin produced by every strain of diphtheria bacilli. The same was true of the tetanus bacillus. The extracellular toxins produced by these two bacilli were so much more powerful than the endotoxins that we did not need to concern ourselves with neutralizing them. In immunization both were alike. A subcutaneous injection gave immunity for ten to twenty days. A second injection added a somewhat shorter period of immunity. The use of antitoxins, however, varied. In diphtheria the disease of the local tissues attacked was at first of chief importance and then later the widespread action of the poison. In tetanus the local tissue involved was of no importance except as a place for the production of the poison. The central nervous system was the point of danger. In diphtheria we wished to reach all tissues of the body with an especial importance of the local tissues. Experimentation had shown that given subcutaneously the antitoxin was gradually absorbed during a period of two to four days. Even in the muscles it was more quickly taken into the blood, but still required two to four hours. Moderate cases should therefore receive the same amount or more intravenously. It was not necessary to repeat the dose, as the antitoxin remained for several days. When a suitable dose was given a later dose, while harmless, was also useless. A unit given intravenously was worth five given subcutaneously.

In developed tetanus experience with animals had shown that where the subcutaneous injection always failed, and the intravenous usually did, that the intraspinal generally succeeded. These results were so striking in a series of experiments that the speaker had for a year advocated the intraspinal injection as absolutely essential. The canal having been tapped five to ten thousand units were injected. The serum should be thin so as to pass up the canal to the ventricles. An intravenous injection of the same amount was given to immediately free the blood of toxin. The intraspinal injection was repeated at the end of twenty-four hours, as by that time the antitoxin had largely passed into the blood. This might not be necessary. In both diphtheria and tetanus the size of the patient and the severity of the disease were the controlling factors in the dosage.

When we used the sera to influence infections due to the organisms causing disease chiefly by their endotoxins we met many difficulties. The strains differed among themselves and we had no such perfect antidote as we had for the extracellular toxin. Indeed we had to satisfy ourselves chiefly with destroying the bacteria rather than neutralizing their poisons. Again we had great difficulties in standardizing the sera and we could accumulate the same amount of protective substance in a cubic centimeter. The methods of administration differed as in the case of antitoxins. In cerebrospinal meningitis the disease was chiefly located on the surface of the cord and brain and their membranes. To reach these we must inject intraspinally. As the protective bodies passed to the blood and did not return we must repeat the injections daily until the disease had terminated. The strains of meningococci were much alike, so that by injecting animals with a mixture of strains we could obtain a single serum suitable for all. Much of the serum used was very weak in antibodies. At present its strength was estimated by its complement fixing power. The pneumococci had been found to fall into many distinct groups, and not only did the serum stimulated by the injection of the strains of one group fail to have any influence on the infection produced by the strains of other groups, but many of the strains seemed to be untouched by sera from animals who had been treated by them. Thus Cole has shown that in New York only about one-fourth of the cases of pneumonia could be influenced by sera. The antipneumococcus sera are given intravenously in large doses of from 100 to 200 c.c. and repeated once or twice. In infections due to group one, the sera undoubtedly had some value. The antistreptococcus sera were similar to the antipneumococcus sera. The streptococci also fell in groups. The best we could do was to have polyvalent sera for the main types. It was very important in both pneumococcus and streptococcus infections to promptly identify the type of organism. The other sera for infections prevalent in this region were at present in the experimental stage.

There was an increasing use of human sera. That from normal persons was used to prevent hemorrhage, increase the supply of blood, and add perhaps antibodies. That from convalescent cases was used for both immunization and treatment. The most frequent use had been in scarlet fever, mumps, and in streptococcus infections. A consideration of the above brief survey taught that it was very important for the physician to have a thorough knowledge of the principles upon which the use of the different sera was founded, if he attempted to use them in treatment.

Dr. F. S. MEARA said that he thought the paper was intensely interesting. The Society was indebted to Dr. Park in so many ways that it was hard to specify particularly what was most valuable. Dr. Park's insistence on the direct method should have been carried out long ago. What was Dr. Park's opinion upon antistreptococcic sera in erysipelas? What would Dr. Park think of using the serum of a patient who had recovered from scarlet fever some time before, even if it had not been a recent case? Did the antibodies endure? These substances in human serum might explain the

dramatic results in the case of a child (quoted by him at a previous meeting) in which the father's blood was injected and cured a long-standing blood infection.

Dr. W. T. LONGCOPE asked if the tetanus antitoxin was concentrated. He said that tetanus antitoxin used many years ago intraspinously did not give good results. Did Dr. Park suppose that one could get more into the spinal canal by using concentrated serum?

Dr. PARK said that in animals he had found pretty small amounts protective intraspinously. He did not see why concentration should make a difference.

Dr. LONGCOPE asked how long after an attack of mumps would it be safe to use the serum on another person. If one took it too early one might get mumps instead of protection.

Dr. PARK said he did not know about that; it would be an interesting question. The serum was used from four to six weeks after an attack.

Dr. ABBE asked in regard to hay fever, which bore upon this subject, if any serum treatment had prevailed.

Dr. BREWER asked if there was any advantage in antitetanus serum given as a prophylactic dose intravenously in small amounts, rather than in moderate amounts under the skin, as a possible preventive.

Dr. PARK said that they did not know how long the antibody would stay in the blood after it was taken from the body. As to the question of intravenous dosage for prophylaxis, there was no advantage in that. What they wanted to do was to store it in the body. It would be eliminated more rapidly by the veins than by the subcutaneous tissues. Hay fever he had not looked into. With the first sera he did not get good results.

Dr. BREWER asked Dr. Park if he knew anything of the organism for scarlet fever.

Dr. PARK said he had done some work and found a streptococcus but the type was not decided.

Dr. SMITH asked in the case of tetanus what guided Dr. Park as to the amount.

Dr. PARK said that one had to get a sufficient quantity to pass up the whole length of the canal, 2,000 in the child and 5,000 in the adult.

Dr. BREWER asked what was the concentration? Would posture make any difference?

Dr. PARK said that the concentration was 2,000 units to the cubic centimeter. He did not think posture had anything to do with it.

Dr. ROPER asked Dr. Park if a definite demonstration had been made of bacteriolytic power on the part of any antipneumococcic serum. So far as he knew the mechanism of recovery was due to bacteriotropic action. The serum of patients convalescing from pneumonia did not seem to have any curative action on cases in which it had been tried. It would be interesting in view of the newer work on the different strains of pneumococci to have this work repeated using what might be called homologous sera. It did not seem to be possible to develop an artificial immunity against the streptococci in a normal individual and transfer it to an infected patient with beneficial results. In a recent case at New York Hospital two transfusions with blood of a vaccinated donor failed to check the increase in the number of organisms to the cubic centimeter in the patient's blood, or to influence the progress of the disease in any way.

Dr. BRANNAN said that at Willard Parker most of the deaths in diphtheria were from bronchopneumonia or sepsis. In these were antistreptococcic sera used as well as antitoxin? He did not see how antitoxin would help in the complications which usually caused death, rather than the diphtheria itself. He should also like to ask about the amount of antitoxin given. At the last meeting of the medical board it was said that the staff men were using enormous amounts of antitoxin for a dose, 20,000 to 30,000 units. Now 5,000 units given early were usually considered sufficient. Were these young men giving unnecessarily large doses?

Dr. MEARA asked if Dr. Park had any cases of streptococcus meningitis which recovered. He had heard there were one or two cases on record. He gathered that no streptococcus serum had been used in the cure.

Dr. PARK said they had recovery in one case. They tried everything. Whether serum had anything to do with the cure, he did not know.

Dr. MEARA asked were there any other authentic cases of recovery.

Dr. ROPER said Dr. Peabody had used serum in one case intraspinally.

Dr. BACON said he had tried sera in case of septicemia and of purulent meningitis but had never had any satisfactory results. Had Dr. Park had any experience with these cases?

Dr. PARK said the results in septicemia were not certain. If one had any infection on the surface one could apply sera because of the antibodies. They had used it in cellulitis and in infected uterus. In septicemia the type of organism must be obtained.

Dr. MEARA asked if intravenous as well as intraspinous injection was given in tetanus.

Dr. PARK said one intravenous dose might be given but it was probably not necessary. They had never found any results in antistreptococcus or antipneumococcus sera. In one interesting case at the Rockefeller Hospital Nicoll injected horse serum into a child with scarlet fever with a temperature of 106°. The child got well. A suitable strain was found to have been used. Some strains might not have responded.

Dr. BRANNAN asked if polyvalent serum could not be used.

Dr. PARK said they would not always get results.

Dr. BRANNAN inquired as to the danger of anaphylaxis in repeated doses of antitoxin.

Dr. PARK said anaphylaxis was impossible with a second dose.

Dr. HUDDLESTON said he had wondered when he heard of 10 c.c. of serum employed by Hess at the difference between that quantity and the amount required to produce immunity against vaccine virus—1 per cent of the weight of the animal. Was there any observation from which the amount of serum in a given case might be judged necessary?

Dr. SMITH asked, in the case of pneumonia, was the Department prepared to supply sera?

Dr. PARK said they had pneumonia I and II, viridans and hemolytic.

Dr. SMITH asked if one could rely on the sera prepared by drug firms.

Dr. PARK said that as to the question of old convalescent sera when years had elapsed, he thought the more recent the disease the greater the accumulation of antitoxin would be.

Dr. MEARA asked would Dr. Park use the serum of some years back?

Dr. PARK said the infant of a woman who had had measles did not get measles for five months. So for twenty years there must often be antibodies.

Dr. MEARA said that might be a very valuable adjunct.

Dr. PARK said he could not tell about bacteriolytic effects. The substances were mostly bacteriotropic and the results could not be the same in the tested types. They had not tried without the cells. The action was mostly opsonic. As to purulent meningitis, they had had very little success. It was a question of the involvement of the ventricles and the cases were almost hopeless. Sophian had had one success but none since. As to Dr. Huddleston's question as to the amount of serum it was hard to give a large dose to a child but a small amount gave protection in mumps. Why he did not know. A small amount of protection might be enough. In giving antitoxin the first 1,000 units did more than all the rest. As regarded the size of the dose, in a severe case a big dose might save. A large dose might act more rapidly. McCollum had given 20,000 units subcutaneously.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

WASHINGTON STATE BOARD OF MEDICAL EXAMINERS.

July, 1914.

[Answer ten (10) questions only in each paper.]

ANATOMY.

1. Describe the sacro iliac articulation, giving ligamentous attachment and nerve supply.
2. Describe the knee joint, giving ligamentous attachments, nerve and blood supply.
3. Describe the heart and its position. Give size and weight of same, with blood supply.
4. Describe the femoral artery, and give its relation to anterior crural nerve and femoral vein.
5. Describe the collateral circulation after ligature of axillary artery.
6. Name the cranial nerves in the order of their passage through cranial foramina.

7. Describe the brachial plexus.
8. What are ductless glands? Name them.
9. Describe the lungs, giving nerve and blood supply.
10. Where is the prostate gland situated? Describe its form and size.
11. Name the muscles of the eyeball and give nerve supply.
12. What is the inguinal canal? Describe the internal and external abdominal ring. Give boundaries of the canal.

PHYSIOLOGY.

1. Define human physiology.
2. Define protoplasm, and give the characteristic properties of living protoplasm.
3. Describe in detail how the placenta performs its functions.
4. Name the nerves concerned in the constriction, and in the dilatation of the pupil of the eye.
5. What is the function of the cerebellum?
6. Describe the phenomena of (*a*) asphyxia, (*b*) syncope, (*c*) sleep.
7. What is the order of occurrence of rigor mortis in the different parts of the body?
8. State the manner in which the blood circulates through the heart, and the lungs, beginning at the right auricle.
9. What would be the effect of a transverse section of (*a*) the anterior root of a spinal nerve, (*b*) the posterior root of a spinal nerve?
10. Describe (*a*) chyme; (*b*) chyle.
11. Why does the blood remain fluid in the body in life and coagulate when shed?
12. What effect is produced on the heart action by stimulation of the cardio inhibitory center?

HISTOLOGY.

1. Describe an erythrocyte. Tell how a normal cell differs in an adult human being from that found in early fetal life.
2. Define anabolism; catabolism. Discuss the vital properties of cells.
3. What layers constitute the blastoderm? (*a*) Name the structures developed from the mesothelium; (*b*) the structures developed from the mesenchyme group of cells.
4. Name the five groups of adult tissues. Describe adipose tissue.
5. Make a diagram of a cross section of the humerus, and then describe the development of the Haversian system of canals.
6. Name the histological characteristics of the cardiac muscle.
7. Describe the Peyer's patches (agminated follicles).
8. Describe a section of the human cornea.
9. Differentiate between a section of the thymus gland, and a like section of a small lymph gland.
10. Describe the structural differences between the Malpighian corpuscles of the spleen and those of the kidneys—make drawing.
11. Describe the histological structure of the lungs.
12. Describe, histologically, tactile corpuscles, where found; Pacinian bodies, where found.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

WASHINGTON STATE BOARD OF MEDICAL EXAMINERS.

July, 1914.

ANATOMY.

1. The *Sacroiliac articulation* is an amphiarthrodial joint formed between the lateral surfaces of the sacrum and ilium. The *ligaments* are: (1) The *anterior sacroiliac*, connecting the anterior surfaces of the sacrum and ilium; (2) the *posterior sacroiliac* passing chiefly downward and inward from the rough part of the ilium to the posterior part of the sacrum; three of the fasciculi are of large size, two of them constitute the *short sacroiliac ligament* and one of them is the *long* or *oblique sacroiliac ligament;* (3) the *interosseus ligaments* which fill up the hollow existing in the posterior of the joint, and are completely covered by the posterior sacroiliac ligament. The *nerve supply* is from the superior gluteal, and sacral plexus.

2. The *knee joint* is a ginglymus, and is formed by the condyles of the femur, the head of the tibia, and the patellæ. "The *external ligaments*: The *anterior* or *ligamentum patellæ* is the continuation of the tendon of the triceps extensor. Above it occupies the apex and rough marking on the lower and posterior surface of the patella; below it is attached to the lower part of the tubercle of the tibia. There is a bursa between the upper part of the tubercle and the ligament. The *posterior ligament* (*ligamentum posticum Winslowii*), broad and thin, covers the back of the joint. It consists of a central and two lateral parts. The lateral parts spring above from the femur above the condyles and are attached below to the head of the tibia. The central part is derived from an expansion of the semi-membranosus tendon, and passes from the inner tuberosity of the tibia to the inner side of the upper part of the outer condyle of the femur. The *internal lateral ligament*, broad and flat, is attached above to the inner condyle of the femur; below, to the margin of the inner tuberosity, to the internal fibrocartilage, and to the inner surface of the shaft of the tibia for 1½ inches. The *long external lateral ligament*, a rounded cord, is attached above to the external condyle of the femur, and below to the external part of the head of the fibula, dividing the biceps tendon into two parts, a bursa intervening. The *short external lateral ligament*, very indistinct, lies parallel and behind the preceding, attached above to the outer condyle of the femur, and below to the styloid process of the fibula. The *capsular ligament*, thin, fills up the intervals between the special ligaments; it is attached to the margins of the articular surfaces of the bones, and blends with the fascia lata of the thigh: above it receives expansions from the vasti (*lateral patellar* ligaments).

"The *Internal Ligaments*: The *anterior* or *external crucial ligament* is attached to the depression in front of the spine of the tibia and to the external semilunar fibrocartilage; it passes upwards, backwards, and outwards to the posterior part of the inner side of the external condyle of the femur. The *posterior* or *internal crucial ligament* is attached to a depression behind the spine of the tibia, to the popliteal notch, and the posterior border of external semilunar fibrocartilage, this latter slip being sometimes called the *ligament of Wrisberg;* it passes upwards, forwards, and inwards, the posterior fibers attached by side of oblique curve of inner condyle, the anterior ones to the fore part of intercondylar fossa and to the anterior part of the outer surface of the inner condyle. The *semilunar cartilages* are thicker at the circumferences than at the central margins, and serve to deepen the cavities for the head of the femur. The *internal semilunar cartilage* is oval in shape, the anteroposterior diameter being the longer. Its anterior extremity is attached to the tibia in front of the anterior crucial ligament, and the posterior extremity in front of the posterior crucial ligament. The *external semilunar cartilage* is nearly circular; its anterior extremity is attached to the tibia in front of the spine, the posterior extremity to the back of the spine." (*Aids to Anatomy.*)

3. A line from the lower border of the second left costal cartilage (one inch from sternum) to upper border of third right costal cartilage (half inch from sternum) represents the *base line;* the *right side* will be a line drawn from right side of upper limit to seventh right chondrosternal articulation; the *lower limit* is a line from this last point to the apex (in fifth intercostal space, three and one-half inches from midline); the *left side*, from left end of upper border to left of apex. The valves are: Aortic, mitral, tricuspid, pulmonary (and Eustachian and coronary)

The *aortic valves* are behind the third intercostal space, close to the left side of the sternum. *Pulmonary valves*, in front of the aortic, behind the junction of the third rib, on the left side, with the sternum. *Tricuspid valves*, behind the middle of the sternum, about the level of the fourth costal cartilage. *Mitral valves* behind the third intercostal space, about one inch to the left of the sternum.

In the *right auricle* are the Eustachian and coronary valves; the former is situated between the anterior margin of the inferior vena cava and the auriculo-ventricular orifice; in the fetus it directs the blood from the inferior vena cava through the foramen ovale into the left auricle; the coronary valve prevents the regurgitation of blood into the coronary sinus during the auricular contraction. In the *right ventricle* are the tricuspid and semilunar valves; the former prevents the blood in the right ventricle from flowing back into the right auricle during ventricular systole; the latter guards the orifice of the pulmonary artery. In the *left ventricle* are the mitral and semilunar valves; the former acts similarly to the tricuspid; the latter guards the orifice

of the aorta. The heart is about 5 x 2½ x 3½ inches, and weighs about ten ounces. It is supplied with blood by the right and left coronary arteries.

4. The *femoral artery* begins at Poupart's ligament; it is the continuation of the external iliac, and passes down the fore part and inner side of the thigh, to terminate at the opening in the adductor magnus at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery.

In the upper part of its course, the anterior crural nerve is on the outer side of the artery, and the femoral vein is to the inner side; lower down the vein passes behind the artery.

5. If the *axillary artery is ligated* (below its subscapular branch), the collateral circulation will take place by: (1) Anastomoses between the branches of the posterior circumflex and the superior profunda; (2) anastomoses between the branches of the subscapular and the superior profunda; (3) anastomoses through various muscular branches of the artery.

6. *Cranial nerves:* I. Olfactory; II. Optic; III. Motor oculi; IV. Pathetic or Trochlear; V. Trifacial; VI. Abducens; VII. Facial; VIII. Auditory; IX. Glossopharyngeal; X. Pneumogastric; XI. Spinal accessory; XII. Hypoglossal.

7. The *brachial plexus* is formed by the union and subsequent division of the anterior divisions of the fifth, sixth, seventh, and eighth cervical and the first dorsal nerves. The union of the fifth and sixth makes the upper trunk; the seventh forms the middle trunk, and the eighth cervical and first dorsal make the lower trunk. Each of these trunks is divided into an anterior and a posterior branch. The anterior branches, from the upper and middle trunks, make the upper or outer cord of the plexus; the anterior branch of the lower trunk becomes the lower or inner cord; the three posterior branches unite to form the posterior or middle cord. The plexus lies between the Scalenus anticus and medius. The *branches* are: (1) Above the clavicle; communicating, muscular, posterior thoracic, and suprascapular. (2) *From outer cord.* External anterior thoracic, musculocutaneous, and outer head of median. (3) *From inner cord:* Internal anterior thoracic, lesser internal cutaneous, ulnar, and inner head of median. (4) *From posterior cord:* Subscapular, circumflex, and musculospiral.

8. The *ductless glands* are glands which do not possess excretory ducts. They are the spleen, thyroid, parathyroids, thymus, suprarenals, carotid, coccygeal, pineal, and pituitary body.

9. "*The lungs* are two in number, occupying the lateral cavities of the chest, separated from each other by the heart and structures within the mediastinum. They accurately fill the cavity of the chest at all times, and are covered by the pleura. They are conical in shape, presenting each a base, apex, two borders, and two surfaces. The apex extends upward above the level of the first rib; the base occupies the convex surface of the diaphragm; the external, or thoracic surface is accurately applied to the wall of the thorax; the inner surface is in contact with the pericardium, and is marked by a depression, the hilum pulmonis, at the root of the lungs. The posterior border rests on either side of the spinal column, and the anterior border is thin and overlaps the pericardium. The root of each lung, situated near its middle, is composed of the following structures, surrounded by a reflection of pleura: Bronchus, pulmonary artery, pulmonary veins, bronchial glands, bronchial vessels, posterior and anterior pulmonary plexuses of nerves, connective tissue. The right lung has three lobes; the left but two, of which the lower is the larger. The *nerves* are derived from the anterior and posterior pulmonary plexuses of the pneumogastric and sympathetic; ganglia are found upon these nerves. The *blood supply* is from the bronchial arteries." (Young's *Handbook of Anatomy*).

10. *Prostate gland* is about 1½ x ¾ x ½ inches, and weighs about three-quarters of an ounce. It resembles a chestnut in size and form. It is situated at the neck of the bladder, and surrounds the first part of the urethra. It consists of fibromuscular (unstriated) tissue with imbedded follicular pouches, the whole enclosed in a firm fibrous capsule, continuous in front with the triangular ligament, and behind with the posterior layer of the deep perineal fascia.

11. *Muscles of the eyeball:* Rectus superior, rectus inferior, rectus externus, rectus internus, obliquus superior, and obliquus inferior; the rectus externus is supplied by the abducens nerve, the superior oblique by the trochlear, and the others by the motor oculi.

12. The *inguinal canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries* are: *In front:* the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind:* the conjointed tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above:* the fibers of the internal oblique and transversalis. *Below:* Poupart's ligament and the transversalis fascia.

Contents: The spermatic cord in the male, and the round ligament in the female.

Internal abdominal ring: "An oval opening lying in the transversalis facia, half way between the anterior superior iliac spine and symphysis pubis, and about 1.3 cm. (½ inch) above Poupart's ligament. Superior and external boundary—curved fibers of transversalis. Inferior and internal boundaries—deep epigastric vessels. Transmits spermatic cord in male—and round ligament in female. Infundibuliform process of fascia transversalis strengthens its opening."

External abdominal ring: "A triangular opening in aponeurosis of external oblique immediately above and just external to crest of os pubis. Bounded, inferiorly, by crest of os pubis—superiorly by intercolumnar fibers, strengthened by intercolumnar fascia; internally by inner or superior pillar; externally by outer or inferior pillar. Transmits spermatic cord in male and round ligament in female."—(Bickham's *Operative Surgery.*)

PHYSIOLOGY.

1. *Human physiology* is that branch of science which deals with the functions of the human body in a state of health.

2. *Protoplasm* is the matter of which cells are made; it is the physiological basis of life, and consists of water, protein, lecithin, cholesterin, phosphates, chlorides, and other substances. Its constitution is unknown. *Properties of living protoplasm:* Irritability, or power of responding to a stimulus; power of movement; power of assimilation; power of growth; power of excretion; power of reproduction.

3. "As a separate organ, *the placenta* dates from the third month of pregnancy, and from that time gradually increases in size until the termination of pregnancy. The chorionic villi lose Langhans' layer of cells, and embed themselves into the interglandular stroma of the decidua basalis, and sometimes penetrate the mouths of the small veins. The syncytium also penetrates the endothelium of the decidual arterioles, and large blood sinuses are thus formed. By this arrangement, the fetal and maternal blood, while kept separate, are brought into such close contact that osmosis may readily occur between them, thus permitting the absorption of nutritive material from the maternal into the fetal circulation, the excretion of urea and other waste products of fetal metabolism, the passage of oxygen to the fetus, and the excretion of carbon dioxide from it. The *functions of the placenta* may be summed up as follows: 1. It is nutritive, allowing of the passage of nutritive material to the fetus. 2. It is respiratory. Oxygen passes to, and carbon dioxide from, the fetus. 3. It is excretory, allowing the escape of urea and other products of fetal metabolism. 4. It has a glycogenic function. Glycogen is stored in its cells for the future use of the fetus. 5. It is iron storing, by which iron in organic combination is passed from the maternal circulation into the fetal circulation to be stored in the liver cells of the fetus, in order to aid in the formation of new colored blood corpuscles."—(Lyle's *Physiology.*)

4. *Constriction* of the pupil is caused by the motor oculi; *dilatation*, by the cervical sympathetic.

5. *Functions of cerebellum:* (1) Coordination of muscular movements; (2) it is concerned in maintaining the equilibrium of the body.

6. *Asphyxia.* "In considering the phenomena of asphyxia, it is necessary to distinguish between rapid asphyxia, produced by complete obstruction to the entrance of air, and slow asphyxia, which is gradually established. The phenomena of asphyxia are divisible into three stages, which are easily observed in animals, especially in the dog. In the *first stage*, called the stage of exaggerated breathing, hyperpnea, the respiration is more rapid and deeper, due to the CO_2; then the phenomena of dyspnea appear, the extraordinary muscles of inspiration and expiration are called into play, the abdominal muscles contract forcibly, the pupils are

small. This stage lasts about a minute. *Second stage*, convulsive stage. Here the inspiratory muscles lose their force, while the expiratory movements become more active; next all the muscles of the body, including the expiratory ones, become convulsed, due to the carbon dioxide stimulating the central nervous system. This stage lasts about a minute. *Third stage*, or stage of exhaustion. This usually comes on suddenly, the carbon dioxide paralyzing the center of respiration; the pupils dilate, the eyelids do not close when the cornea is touched; a state of general calm ensues, which is in marked contrast with the previous agitation; consciousness is abolished; the animal lies motionless and seems dead; occasional inspiratory acts take place, then they become feebler and of a gasping character; finally, the nostrils dilate, the limbs of the animal are extended, opisthotonos ensues, the pulse disappears, and death closes the scene. This state lasts about three minutes. This pulseless condition is properly denominated asphyxia. The phenomena of slow asphyxiation follows the same course, but less rapidly." (Ott's *Physiology.*)

Syncope is the complete, and often sudden, loss of motion and sensation with diminution or suspension of heart pulsations and respiratory movements; it may indicate cardiac disease.

Sleep.—"This phenomenon is one of many instances of the rhythmic activities of the central nervous system. From time to time all animals with a well-developed nervous system go to sleep, during which psychical activity is at its lowest point. To reach this condition the most important favoring factor is an exclusion of all or most of the impulses from the central nervous system. In a well-known case of Strümpell, in which, from a complicated anesthesia, all sensory impulses were limited in their entrance to a single eye and a single ear, the patient could be put to sleep at will by closing the eye and stopping the ear. In addition, sleep has been attributed to the following influences: 1. Chemical influences. 2. Circulatory influences. 3. Histological influences. Those who hold to *chemical influences* in the production of sleep maintain that during normal activity of the body various substances are formed which are circulated in the blood and directly lessen the activity of the nerve cells or indirectly diminish the supply of blood in the brain. In the theories of *circulatory influences* a fatigue of the vasomotor center is looked upon as the cause of the anemia of the brain resulting in sleep. In the third set of theories sleep is supposed to be due to a separation of the dendrites of the brain cells due to an active contraction or to an intrusion of neuroglia cells between them. During sleep the capability of the nervous system to transmit impulses is not entirely lost. The cerebral cortex is most affected, the spinal cord least. The close relation between dreams and external stimuli is well known and it has been proved experimentally that vasomotor changes induced by external stimuli may take place without awakening the sleeper. The period of deep sleep is short and falls within the first two hours after its onset. During this time the pulse and breathing are slower, the intestines and bladder are at rest, the output of carbon dioxide is lessened, and the consumption of oxygen still more so; metabolism is less vigorous and the temperature falls. The respiration is said to become thoracic in type and to take on a more or less pronounced Cheyne-Stokes rhythm. The visual axes are directed upward and inward, but the pupils are contracted. The latter is peculiar, since an absence of light should bring about dilatation. This is connected perhaps with important actions taking place in lower levels of the brain." (Guenther's *Physiology.*)

7. *Rigor mortis* first appears in the muscles of the lower jaw, then spreads to the muscles of the face and neck, then to the muscles of the thorax and abdomen, then to those of the upper extremity, and finally to those of the lower extremity.

8. "The left ventricle pumps the arterial blood through the large arteries, the small arteries, and the arterioles into the systemic capillaries. For the most part between the capillaries and the tissues is the tissue fluid, and across this the tissues acquire the oxygen from the arterial blood and return carbon dioxide to the blood in the capillaries. The blood which leaves the tissues is venous. The venous blood returns from the capillaries through the small veins into the larger veins, and the largest veins pour the blood back into the right auricle. It will thus be seen that the right side of the heart is occupied with the pulmonary circulation and the left side of the heart with the systemic circulation. The right auricle receives the venous blood as it returns from the tissues, and transmits it to the right ventricle. The function of the right ventricle is to pump the venous blood through the pulmonary arteries into the lung capillaries, where the venous blood becomes oxygenated. The oxygenated blood returns by the pulmonary veins to the left auricle, and the arterial blood is then received into the left ventricle."—(Lyle's *Physiology.*)

9. Transverse section of the *anterior root* of a spinal nerve causes loss of motion and degeneration of the peripheral portion of the anterior root fibers; the sensory fibers of the posterior root are not affected.

Transverse section of the *posterior root* of a spinal nerve causes loss of sensation and degeneration, which latter differs according as the section is made on the proximal or peripheral side of the ganglion. If the section is made between the cord and the ganglion, degeneration only occurs in the piece severed from the ganglion, but connected with the cord. If the section is made beyond the ganglion, degeneration occurs in the fibers peripheral to the lesion.

10. *Chyme* is a thick, acid liquid, which is the result of gastric digestion; it consists of proteids, salts, liquefied fat, and undigested matter. It is passed forward into the duodenum.

Chyle is that portion of the lymph which is found in the small intestine during the period of digestion; it is mainly composed of water, proteids, and fats, the latter giving it a milky appearance.

11. The reason why the blood remains fluid in the body during life and coagulates when shed, is because during life the blood is kept moving and because the fibrin enzyme which normally exists in the blood plasma is neutralized by the antithrombin which is secreted by the liver cells.

12. *Stimulation of the cardioinhibitory center* inhibits or restrains the action of the heart; the frequency of the heart's action is diminished, and the strength of its contractions is lessened.

HISTOLOGY.

1. An *erythrocyte* is a non-nucleated, circular, concave disc; it contains red coloring matter, *hemoglobin;* and is about 1/3200 inch in diameter. In *adult* life it is non-nucleated; in fetal life it is nucleated.

2. *Metabolism* is the entire series of changes that occur in a cell or organism during the processes of nutrition. It is of two kinds: (1) Assimilative or constructive (anabolism), and (2) destructive (catabolism).

The *manifestations of cell life* are: Movement, ingestion, assimilation, excretion, growth, irritability, and reproduction.

3. The *blastoderm* has three layers—the ectoderm, mesoderm, and entoderm.

From the *mesothelium* are derived the flattened epithelioid cells which line the various serous cavities of the body.

From the *mesenchyme* are derived the various connective tissue cells such as bone, dentine, cartilage, fibrous and areolar tissue, lymph, and blood.

4. *The five groups of adult tissue are:* (1) Epithelial tissues, (2) connective tissues, (3) blood, (4) muscle tissue, and (5) nerve tissue.

Adipose tissue is a form of connective tissue and consists of vesicles filled with fat; these vesicles are collected into lobules, and vary in shape, being round or oval when not subjected to pressure, but polyhedral when compressed. The cell has an oval flattened nucleus situated just within the thin membrane which surrounds the cell.

5. For illustration, see Bailey's *Histology.* 3d Edition, 1910, fig. 102, p. 167.

Transverse section of compact bone from shaft of humerus (From Bailey's *Histology*):

"All bone is at first of the spongy variety. When this is to be converted into compact bone, there is first absorption of bone by osteoblasts, with increase in size of the marrow spaces and reduction of their walls to thin plates. These spaces are now known as Haversian spaces. Within these new bone is deposited. This is done by osteoblasts which lay down layer within layer of bone until the Haversian space is reduced to a mere channel, the Haversian canal. In this way are formed the Haversian canals and the Haversian systems of lamellæ. Some of the interstitial lamellæ are the remains of the spongy bone which was not quite removed in the enlargement of the primary marrow spaces to form the Haversian spaces; other interstitial lamellæ appear to be early formed Haversian lamellæ which

have been more or less replaced by Haversian lamellæ formed later."

6. *Cardiac muscle* consists of fibers of short, stubby cylindrical form, possessing striations and a delicate sheath, but no regular sarcolemma. There is a single, oval nucleus to each cell; this nucleus is centrally situated and is surrounded by pigment granules.

7. *Peyer's patches* are aggregations of solitary glands, measuring from about half an inch to three inches in length; they are found mainly in the ileum, but also occur in the duodenum, and jejunum; they are situated lengthwise in the intestine, and are located opposite to the mesenteric attachment. Each patch is surrounded by a group of the crypts of Lieberkühn. There are said to be from 30 to 50 of these patches in the human intestine. As a rule, they have no villi on their surface.

8. The *cornea* consists of five layers: (1) An anterior layer of stratified squamous epithelium; (2) an anterior elastic membrane, also known as Bowman's membrane; (3) the substantia propria consisting of connective tissue fibrils which are cemented together to form bundles and lamellæ; (4) the posterior elastic membrane of Descemet, similar to the anterior elastic membrane, but thinner; (5) the posterior endothelium of Descemet, consisting of one layer of flat hexagonal cells.

9. The *thymus* contains spherical or oval bodies of concentrically arranged epithelial cells known as Hassall's corpuscles; nucleated red blood corpuscles may be seen in the thymus; and the lymph nodules contain no germinal centers. The *lymph gland* does not contain Hassall's corpuscles and it has no nucleated red corpuscles; furthermore the lymph nodules contain germinal centers.

10. The *Malpighian corpuscles of the spleen* "are distributed throughout the splenic pulp. Each splenic corpuscle contains one or more small arteries. These usually run near the periphery of the corpuscle; more rarely they lie at the center. Except for its relation to the blood-vessels, the splenic corpuscle is quite similar in structure to a lymph nodule. It consists of lymphoid cells so closely packed as completely to obscure the underlying reticulum. In a child's spleen the center of each corpuscle shows a distinct germinal center. In the adult human spleen germ centers are rarely seen." (Bailey's *Histology*).

The *Malpighian corpuscle of the kidney* "is spheroidal, and has a diameter of from 120 to 200μ. The structure of the Malpighian body can be best understood by reference to its development. During the development of the uriniferous tubules and of the blood-vessels of the kidney, the growing end of a vessel meets the growing end of a tubule in such a way that there is an invagination of the tubule by the blood-vessel. The result is that the end of the vessel which develops a tuft-like network of capillaries—the *glomerulus*—comes to lie within the expanded end of the tubule, which thus forms a two layered capsule for the glomerulus. One layer of the capsule closely invests the tuft of capillaries, dipping down into it and separating the groups of capillaries. This layer by modification of the original epithelium of the tubule is finally composed of a single layer of flat epithelial cells with projecting nuclei. The outer layer of the capsule lies against the delicate connective tissue which surrounds the Malpighian body. This layer consists of a similar though slightly higher epithelium and is known as *Bowman's capsule*. Between the glomerular layer of the capsule and Bowman's capsule proper is a space which represents the beginning of the lumen of the uriniferous tubule, the epithelium of Bowman's capsule being directly continuous with that of the neck of the tubule." (Bailey's *Histology*).

For illustrations see Bailey's *Histology* 3d Edition, 1910, figs. 95 and 198, pp. 159 and 289.

11. *The structure of the lungs.*—"In the lungs the bronchi branch in a tree-like manner, the final ramifications opening into the pulmonary cells. The larger intrapulmonary bronchi are lined by columnar ciliated epithelium resting on a basement membrane. Lying under this basement membrane are longitudinally disposed elastic fibers with loose connective tissue. More externally is a layer of smooth muscle fibers arranged circularly, the bronchial muscle. External to the bronchial muscle is a fibrous coat containing scattered, irregular plates of hyaline cartilage. The smaller bronchi (bronchioles) have no cartilaginous plates, but their muscular coat is well marked. Each bronchiole leads into a small number (three or four) of wider thin-walled spaces, lined by flattened epithelium, and called atria. Out of each atrium open two or three blind diverticula, each of which is called an infundibulum. The walls of the infundibula are studded with hemispherical sacs known as alveoli, which are lined by flattened, non-nucleated, epithelial cells. Between adjacent alveoli there is a dense network of capillaries, supported by a small amount of fine connective and elastic tissue; the network of capillaries is thus common to the two adjacent air cells, and the blood in the capillaries is separated from the air in the alveoli merely by two thin layers of epithelium. In birds, even the alveolar epithelium appears to be absent, the blood and air being separated solely by the capillary wall." (From Bainbridge and Menzies', *Essentials of Physiology.*)

12. *"Tactile corpuscles.*—These consist of connective tissue which forms a capsule, from which are given off membranous partitions or septa. After winding around the corpuscle the axis-cylinder enters it, and terminates in an enlargement. Tactile corpuscles occur in the papillæ of the skin of the hand, foot, front of the forearm, lips, and nipple; also in the mucous membrane of the tip of the tongue and the conjunctiva lining the eyelids.

"Pacinian corpuscles.—These are also called corpuscles of *Vater*. Each corpuscle consists of concentrically arranged layers of connective tissue, with nucleated cells. A medullary nerve-fiber enters at one end and passes into an interior space which contains a transparent substance; here only the axis-cylinder is present. This terminates at the end of the corpuscles in an enlargement or in minute branches, an arborization. These corpuscles exist in the subcutaneous tissue of the palm of the hand and sole of the foot, and in the penis. Observers have also found them in the pancreas, lymphatic glands, and thyroid." (Raymond's *Physiology.*)

(To be continued.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†
Alabama*	W. H. Sanders, Montgomery	Montgomery
Arizona*	J. W. Thomas, Phoenix	Phoenix
Arkansas	W. S. Stewart, Pine Bluff	Little Rock
California	C. B. Pinkham, Sacramento	Los Angeles Dec 14
Colorado	David A. Strickler, Empire Building, Denver	Denver Oct. 5
Connecticut*	Chas. A. Tuttle, New Haven	New Haven Nov. 9
Delaware	J. H. Wilson, Dover	Dover Dec. 11
Dist. of Col'bia	E. P. Copeland, Washington	Washington Oct 12
Florida*	E. W. Warren, Palatka	Jacksonville Dec. 7
Georgia	C. T. Nolan, Marietta	Atlanta Oct 12
Idaho*	J. F. Schmershall, Jerome	Wallace Oct. 5
Illinois	C. S. Drake, Springfield	Chicago
Indiana	W. T. Gott, Crawfordsville	Indianapolis Jan. 11
Iowa	G. H. Sumner, Des Moines	Des Moines
Kansas	H. A. Dykes, Lebanon	Topeka Oct. 12
Kentucky	J. N. McCormack, Bowling Green	Louisville
Louisiana	E. L. Leekert, New Orleans	New Orleans Dec. 2
Maine	F. W. Searle, Portland	Portland Nov. 9
Maryland	J. McP. Scott, Hagerstown	Baltimore Dec. 14
Massachusetts*	W. P. Bowers, State House, Boston	Boston Sept. 14
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing Oct. 12
Minnesota	T. McDavitt, St. Paul	Minneapolis
Mississippi	E. H. Galloway, Jackson	Jackson Oct. 5
Missouri	J. A. B. Adcock, Jefferson City	Kansas City Sept. 28
Montana*	Wm. C. Riddell, Helena	Helena Oct. 5
Nebraska	H. B. Cummins, Seward	Lincoln
Nevada	S. I. Lee, Carson City	Carson City Nov. 1
N. Hampshire	Walter T. Crosby, Manchester	Concord Sept. 15
New Jersey	H. G. Norton, Trenton	Trenton Oct. 19
New Mexico	W. E. Kaser, East Las Vegas	Santa Fe
New York	H. H. Horner, Univ. of State of New York, Albany	New York, Albany, Syracuse, Buffalo — Oct 5
N. Carolina	H. A. Royster, Raleigh	Raleigh June
N. Dakota	G. M. Williamson, Grand Forks	Grand Forks Jan 4
Ohio	Geo. H. Matson, Columbus	Columbus
Oklahoma	J. W. Duke, Guthrie	Oklahoma City Oct. 12

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PRINCIPLES OF BACTERIOLOGY. By A. C. ABBOTT, M.D. Published by Lea & Febiger, Philadelphia and New York. Ninth edition; thoroughly revised; with 113 illustrations, 28 of which are colored; 650 pages. Price, $2.75.

BEITRAGE ZUR KLINIK DER INFEKTIONSKRANKHEITEN UND ZUR IMMUNITÄTSFORSCHUNG. By Professor Dr. L. BRAUER. Published by Curt Kabitzsch in Würzburg; 124 pages.

OPERATIVE GYNECOLGY. By HARRY STURGEON CROSSEN, M.D., F.A., C.S. Published by C. V. Mosby Company, St. Louis. Seven hundred and seventy original illustrations; 670 pages. Price, $7.50.

HUMAN PHYSIOLOGY. By Professor LUIGI LUCIANI. Published by Macmillan & Co., Ltd., St. Martin's street, London. With a preface by J. N. Langley, F.R.S. In five volumes; Vol. 3; 667 pages; price, $5.00.

GENERAL SURGERY. Edited by JOHN B. MURPHY, A.M., M.D., LL.D., F.R., C.S. Published by The Year Book Publishers, 327 S. La Salle street, Chicago, Ill. Vol. 2; 602 pages; price, $2.00.

MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN GLAISTER. Published by William Wood & Company; third edition, with 137 illustrations and one colored plate. Price, $5.00 net; 857 pages.

THE INTERVERTEBRAL FORAMINA IN MAN. By HAROLD SWANBERG. Published by Scientific Publishing Co., Chicago, Ill. Illustrated by 11 original full-page plates; 95 pages. Price, $1.75.

THE ALLIGATOR AND ITS ALLIES. By A. M. REESE. Published by G. P. Putnam's Sons, 2-6 West 45th St., New York. With 62 figures and 28 plates; 358 pages. Price, $2.50.

MODERN MEDICINE. Its Theory and Practice. Edited by Sir WILLIAM OSLER, Bart., M.D., F. R. S., and THOMAS MCCRAE, M.D. Published by Lea & Febiger, Philadelphia and New York. Volume 5; second edition; thoroughly revised; illustrated; 1092 pages.

GYNECOLOGY OF OBSTETRICS. By DAVID HADDEN. Published by the Macmillan Company, New York. Illustrated; 198 pages; price $3.50.

SCHOOL HYGIENE. By LEO BURGERSTEIN. Published by Frederick A. Stokes Company, New York. With 43 illustrations and diagrams; 188 pages.

THE INTERNATIONAL MEDICAL ANNUAL. Published by William Wood & Company, New York City. Illustrated; 760 pages; price, $4.00 net.

REPORT OF THE HEALTH OFFICER OF THE PORT OF NEW YORK. Transmitted to the Legislature, January 14, 1915. Printers, J. B. Lyon Company, Albany; 264 pages.

WHAT EVERY MOTHER SHOULD KNOW. By CHARLES G. KERLEY, M.D. Published by Paul B. Hoeber, 67-69 East Fifty-ninth Street, City; 107 pages; price, 35 cents.

OCCUPATIONAL AFFECTIONS OF THE SKIN. By R. PROSSER WHITE, M.D. Published by Paul B. Hoeber, 67-69 East Fifty-ninth Street, City; 165 pages; price $2.00 net.

THE CLINICAL ANATOMY OF THE GASTROINTESTINAL TRACT. By T. WINGATE TODD, M.D., Ch.B. Published by Longmans, Green & Company, London, New York, Bombay, etc.; 264 pages; price, $1.75 net.

WAR SURGERY. By EDMUND DELORME. Published by Paul B. Hoeber, 67-69 East Fifty-ninth Street, City. With illustrations; 248 pages; price, $1.50 net.

THE OPERATIVE TREATMENT OF CHRONIC INTESTINAL STASIS. By SIR W. ARBUTHNOT LANE, Bart., M.S. Published by the Chicago Medical Book Company, 1915. Third edition. Price, $4.00; 201 pages.

CHIRURGISCHE OPERATIONSLEHRE, für Studierende und Artze. Von Prof. Dr. FRIEDRICH PELS LEUSDEN. Published by Urban & Schwarzenberg. Zweite, wesentlich verbesserte Auflage. Mit 766 Abbildungen; 788 pages.

PRAKTIKUM DER CHIRURGIE. Von Dr. O. NORDMANN. Published by Urban & Schwarzenberg. II. Teil. Spezielle Chirurgie. Mit 161 teils farbigen Abbildungen; 632 pages.

Therapeutic Hints.

Treatment of Colitis in Infancy.—Hutinel is said to recommend irrigations of the colon with the following solution:

℞ Solution of hydrogen dioxide, 50 grams.
Sodium phosphate, 3 grams.
Sodium chloride, 5 grams.
Sodium bicarbonate, 0.5 gram.
Boiled water, 1 liter.

—*Riforma Medica.*

For Intestinal Indigestion.—The following is said to be efficient:

℞ Calcined magnesia.
Cream of tartar,
Flowers of sulphur, āā 30 grams.

M. et Sig.: One teaspoonful every morning on a fasting stomach.—*Riforma Medica.*

The Treatment of Graves' Disease.—Rummo is said to prescribe the following:

℞ Iron bromide.
Zinc bromide.
Monobromated camphor, āā 1.50 grams.
Calcium glycerophosphate.
Ergotin, āā 6 grams.
Zinc phosphide.
Extract of cannabis indica.
Extract of belladonna, āā 0.60 gram.
Extract of coca, q.s.

M. et div. in pilulæ, No. 120.

S.: One pill three times a day.—*Riforma Medica.*

The Treatment of Tuberculous Peritonitis.—M. Bonnamour is credited with the use of the following ointment:

℞ Iodine, 2 grams.
Potassium iodide, 2 grams.
Petrolatum, 30 grams.

—*Journal de Médecine et de Chirurgie.*

Treatment of Ascites.—Litard is credited with the following formula:

℞ Tincture of digitalis, 5 grams.
Tincture of adonis vernalis, 10 grams.
Tincture of jaborandi, 15 grams.

M. et Sig.: Twenty-five drops three times a day. —*Riforma Medica.*

Treatment of Catarrhal Conjunctivitis.—P. Prélat recommends the use of the following collyrium:

℞ Ammonium chloride, 0.07 gram.
Zinc sulphate, 0.15 gram.
Camphor,
Saffron, āā 0.01 gram.
Boiled distilled water, 15 grams.

This solution is known as the "yellow eye wash." It sometimes causes a painful reaction, in which case the amounts of ammonium chloride and of zinc sulphate should be reduced.—*Bulletin Général de Thérapeutique.*

Sulphur in the Treatment of Typhoid Fever.—Goubeau reports that he has treated a series of thirty-one cases of typhoid fever with this element without a single fatality. Following the initial purgation by means of calomel there are given by mouth five or six times daily cachets or powders each containing one gram of flowers of sulphur. During the first fifteen days of convalescence the drug is given in gradually diminishing doses. The effect of this method of treatment is to lower the temperature and to diminish the intensity of all the other symptoms.—*Bulletin Général de Thérapeutique.*

THE CLEARING HOUSE FOR MENTAL DEFECTIVES.

BY MAX G. SCHLAPP, M.D.,

NEW YORK.

DIRECTOR OF THE CLEARING HOUSE FOR MENTAL DEFECTIVES; PROFESSOR OF NEUROPATHOLOGY, NEW YORK POST-GRADUATE HOSPITAL AND MEDICAL SCHOOL.

THE present public interest in the care of the mentally defective seems to be the culmination of a growing feeling among social workers of all types, as well as among physicians interested in this field of work, that some underlying cause must be found for the failure of so many, both adult and juvenile, to hold among their companions the place normally theirs, both in work and in school.

History of Development.—The official recognition of this need in New York City came from the judges of the Children's Court, before whom were taken juveniles, charged with offenses which seemed to be due to mental or moral defects, rather than to causes correctable by the penalties usually imposed. These children were first examined at the instigation of the Society for the Prevention of Cruelty to Children. At about this time, Mrs. William K. Vanderbilt became interested in the general subject and gave freely of her attention and money to the extension of the work. Through her generosity it became possible to develop the work of the Clearing House, and also to secure the services of a proper medical staff upon Randall's Island.

As a result of her efforts, Commissioner Drummond, of the Department of Public Charities, awoke to the necessity for the establishment of such an examination in connection with the feeble-minded and epileptic, who were constantly transferred to his department from other institutions, or for whom admission to the institutions under his control was desired by parents and social workers.

Previous to this time there had been no definite examination of such applicants. The statement of any private practitioner, whether a competent neurologist or not, had been accepted as sufficient authority for the condemnation of a patient to institutional life for so long as his natural guardians might choose, or for an indefinite time, and in many instances for all life.

The problem of finding a suitable place for carrying on the work of these examinations was solved by the generosity of the board of trustees of the Post-Graduate Hospital. The Clearing House is established in the hospital, and patients are admitted through the dispensary, as is done with its own clinics. The work of the Clearing House has been greatly facilitated by this intimate connection with a thoroughly equipped hospital. Patients may readily be transferred, for instance to the eye or ear clinic for treatment of defects of the special senses; Wassermann tests may be given, and any physical disability may be properly treated in conjunction with the examination given at the Clearing House. The extent of our obligation to the Post-Graduate Hospital is thus obvious.

An advisory committee of influential women was organized, later, with Mrs. Charles Dana Gibson as chairman; its aim being the support and direction of efforts in behalf of this work. It is with deep gratitude that the interest and assistance which this committee has rendered the Clearing House are here acknowledged.

Purpose.—The underlying purpose of the Clearing House is to deal with the problem presented by the mentally unfit members of the community, in order that the most dangerous of them may be eliminated from among the possibilities of menace, and in order that the least harmful may be adjusted to their surroundings. Aside from giving this practical help to the people of New York, the institution is also gathering definite information concerning the numbers of such defectives within the city limits. Later this information will prove its usefulness by forcing into prominence the question of proper segregation.

When the petty details which so far have obstructed the work, are relegated to the background and the question is viewed from the broad standpoint of the future welfare of the race, it presents a striking likeness to the struggle which during the past two decades marked the effort for improved, that is, scientific and humanitarian, treament of the insane. The contrast between the present kindly and comprehensive care of the insane and the neglected or abused state into which they invariably fell when left to the mercies of indifference, greed or chance, shows the absurdity of any claim that the present haphazard care which is vouchsafed the feebleminded is the best possible. It is a fact beyond dispute that the Clearing House is an important step taken toward the ultimate goal of an adequate solution of this great problem.

It seems advisable to emphasize, at this point, the fact that the work described in the following paper is not only serving its current purpose as well as may be under the circumstances, but that, also, it is amassing valuable information upon which may be based future research into the cause of mental defects. Without such knowledge there would be no hope of ever lessening this evil which so notably and increasingly afflicts the human race.

The scientific detention, diagnosis, registration of and research into mental deficiency is the aim of the Clearing House for Mental Defectives, and in carrying out this purpose the following plan should be developed:

All persons found to be socially unfit, actually or potentially, as a result of suspected mental de-

fects, should be referred to the Clearing House by the agent of the department or society which originally discovers them, and in the Clearing House they should be subjected to the following procedure: (1) Complete registration and identification of the person by means of photographs, fingerprints and mental and physical measurements; (2) diagnosis; (3) recommendations for care, treatment or training proper to each case; (4) follow-up work.

1. *Registration.*—First should be noted the name, age, occupation, personal, family, and social history of each applicant, so that a fair conception of his status in the community may be available at a glance. Then his photograph should be made, and, if he has any unusual physical deformities or markings these should be photographed and their cause noted if known. Fingerprints and Bertillon measurements should be made and recorded.

Such measurements were undertaken when the Clearing House was inaugurated, but lack of help made it necessary to abandon them. At present photographs are only made in the most important cases showing unusual conditions.

The primary importance of complete registration and identification at once becomes apparent if we recall that it is from just this class of mental incompetents that the community's criminality, degeneracy, and pauperism develop. The percentage of feebleminded among social offenders is very high, and it is accepted as axiomatic that every mentally defective person is a potential criminal. If the finger prints of all feebleminded persons were on file at the Clearing House, the prints made or secured by the police in any baffling case could be easily sent there for the proper comparison and identification. When the offender has been traced, thus a great service would have been rendered to the police, and later the Clearing House records would be of important value in the courts, as guides in the determination of mental responsibility and the just disposition of those found guilty of crime.

2. *Diagnosis.*—After registration and identification, patients are sent to the psychologist, who examines them by the various mental tests, and determines whether or not any mental retardation is present. They then are sent to the psychiatrist for further examination, to determine the nature of, and if possible, the cause of such retardations as may have been discovered. These may be due to actual mental defects, or to physical causes which often are amenable to treatment, or to mental instability which may be attributed to various factors and often may be curable.

Many cases are referred to the Clearing House, also, in which mentality apparently is not retarded; in fact, cases in which exists mental activity amounting to precocity are not unknown there, but the affective side of the patient's life in such instances is deranged, thereby causing him to commit acts which in themselves are menacing to the community. Sometimes such derangements are only temporary in character, and frequently they are the result of emotional disturbance during the period of adolescence. Persons so afflicted may become sexual perverts, kleptomaniacs, pyromaniacs, moral imbeciles, and in some cases must be segregated in order that they themselves and others may be guarded from grave social dangers. There can be no question of the necessity for their early discovery.

Very little is known about these phases of affective derangement, even by expert psychiatrists, and many cases unfortunately are diagnosed as either feebleminded or insane that really are neither, but are amenable only to treatment quite different from that which is effective in such diseases. Only the specialist can differentiate properly between such conditions and trace to its cause in each case the psychopathic sympton, obvious, perhaps, to the most superficial observer.

On the other hand, nothing is more important than that the diagnosis in each case should be based only upon the most scientific knowledge and highest technical skill, for a wrong diagnosis may often mean treatment so improper that it may result in untold danger to an individual or to society. These are of the many cases which especially demand expert and patient observation before any recommendation properly may be made for their treatment and segregation.

Upon this diagnosis, naturally, depends the course to be pursued in the treatment of the individual. Particularly among children there are many cases which show a decided mental retardation due to some removable cause and which therefore are not actual cases of deficiency. As an illustration may be cited the case of a boy who was sent to the Clearing House.

He was fourteen years old. His mother stated that he had been perfectly normal, well behaved and regularly promoted in school, previous to his eleventh birthday. At about that time he began to complain of headaches, became very irritable and fell so far below his school grade as to be lower at the end of the year than he had been at its beginning. He was placed in an ungraded class, and, later, it was decided to take him to the Children's Court on the charge of incorrigibility. His teacher, however, advised sending him first to the Clearing House.

There his retardation was found to equal the lack of three years' normal mental growth, and that this mental retardation, his decided mental irritability and his incorrigibility all were due to the irritating effects of a chronic abscess in the frontal sinuses. By means of an operation the pus and necrotic bone, which had existed from the time the symptoms began, were removed.

Soon afterward the boy began to improve, and from the latest reports which have been received of his case at the Clearing House, it is evident that he has recovered entirely and to-day is normally adjusting himself to his environment. From this case it can be seen that conditions exist which simulate feeblemindedness and which will result disastrously if they are not recognized and corrected.

Another vital function of the psychiatrist is the separation of the vicious from the harmless feebleminded. Of course, those who are a menace to the community should be given preference for institutional care. There is a real necessity for the separation of the delinquent mental defective from the dependent and non-delinquent mental defective.

This could also be done at the Clearing House. In fact, it is being done there now to some extent, Moreover, the Clearing House can be of great help to the courts in determining whether individuals who have committed crimes are, or are not, mentally deficient, as well as recommending proper care and treatment for those who are. The statistics for the last last two years show that in about one case in ten of those brought to the Clearing House come directly from the courts. By far the greatest num-

ber of these are sent from the Children's Courts and referred to the psychiatrist for examination and recommendation by the probation officers and judges. In the twenty-one months following its establishment, 521 court cases were thus taken at the Clearing House. Many of these delinquents were repeaters who had appeared in the courts two, three or four times, and had simply passed from one term of imprisonment or probation to another without being recognized as inherently defective. Besides the courts, the agencies that have contributed the greatest number of patients to the clinic are the charities, the schools, the hospitals, the orphan asylums, and the various homes of refuge. About one case in eleven is referred to us directly by the schools, and about an equal number come from the charitable societies. In the year 1913, patients were referred from 150 different sources. Owing to the lack of a statistician, the exact figures for 1914 are not yet available.

At present the Clearing House, while not able to carry out its ideals in a manner satisfactory to itself, nevertheless is really serving the community at large by doing as many things as its limited equipment will allow. In all essential points it is doing as well as is humanly possible under the existing circumstances.

Patients are being sent to the clinic daily by the courts, private charities, children's societies, settlements, school teachers, probation officers, and many other social workers. Not only are the physicians asked to diagnose degrees of deficiency and to help in the commitment of those clearly defective, but also to examine many who, after careful investigation, are found to be mentally normal. Such negative findings are surely contributions as valuable both to the individual and to the society concerned with them as is the other function of the Clearing House—that of detecting those who actually are feebleminded. Many agencies which refer cases to us have been kind enough to state before the State Commission and to me personally that they count upon our co-operative work to help them to determine the true character of those with whom they have to deal.

In the year between October 1, 1912, and October 1, 1913, 5000 visits were made by patients, for the purpose of treatment or examination at the Clearing House, and in the following year, *i. e.* from October 1, 1913, to October 1, 1914, this number increased to more than 7800. This proves the growing value of the institution to the community and, therefore, the increasing necessity of properly equipping and supporting it to meet the increasing demands upon its services.

At the present time many individuals are sent to Randall's Island from different hospitals and institutions without a definite preliminary examination, or, at least, unaccompanied by any report of such an examination. There is no way of ascertaining anything about these patients after they have been sent to Randall's Island unless members of their families call on them, and it is difficult to get the information necessary to the records even from such members of their families. Therefore, it seems advisable that all cases suspected of being feebleminded should undergo a careful examination at the Clearing House before they are admitted to Randall's Island.

This would seem to be especially imperative in the cases of children who come under the jurisdiction of the various juvenile courts for delinquencies of such a nature as to justify the suspicion of mental defect. In such cases it is highly important that a thorough and careful analysis of the child's condition be made after an extended period of observation and under a uniform system of medical inspection.

Because of their mental condition the inmates of our institutions for defectives cannot explain to the doctors their symptoms, and medical men of special training and long experience are therefore required for the medical treatment and general care of these defectives. Only through the existence of a uniform staff of physicians in touch with the work of all the city institutions of this nature, including the courts, the Clearing House and Randall's Island can we hope to have the best possible work done.

This also is true in the courts for adult offenders, particularly as regards cases of prostitution, vagrancy, and crime which give strong reason for suspecting mental deficiency as the fundamental cause of the delinquency. Such cases are now referred to the Clearing House for diagnosis, as we have before pointed out, but because of the lack of facilities and the lack of uniform medical control the examination cannot be extended over a period of time sufficient to insure accurate observation.

3. *Recommendation for Care and Treatment.*—It distinctly must be understood that recommendation for institutional care is not at all the only nor the most important function of the Clearing House. The institutions for mental defectives in New York State accommodate, approximately, 4900, and the best authorities estimate that there are almost an equal number improperly cared for in our prisons, reformatories and almshouses. As it also is regarded conservative to estimate the total number of defectives in the State at 30,000, about one-half of them are residents of Greater New York, it is impossible, of course, even to consider institutional treatment for all as a present remedy. But because of these inadequate accommodations it is the more important that a careful and scientific diagnosis be made of all cases, precedent to commitment, in order that those who, because of utter dependency or malicious delinquency, are a menace to society may be given the preference in our institutions.

It is, therefore, also of primary importance that all other cases, not so placed in institutions, should be studied carefully, and, if possible, treated so as to fit them to adapt themselves to their environments, or that an available environment that is most suited to their limited capacity for self respect and self support shall be recommended for them. This would include, for instance, the adjustment of court cases through the children's societies and the adult probation agencies, and the cross-references of such cases to the various homes, vacation centers, and social clubs conducted by our private charities. In many instances clinical treatment, such as is offered by the various hospitals and dispensaries should be made use of.

In other words, where it is not feasible to segregate all who are feebleminded, it is necessary to have such an organization as the Clearing House to select for institutional care those who form the greatest source of peril to the community, and to help the others to maintain as normal a social life as is within their capacity, adapting the form of such help to the particular needs of each individual and determining these by careful educational, psychological, medical, and psychiatric research.

Follow-up Work.—Although it properly may be regarded as a most important adjunct of the work, as yet it has been possible to inaugurate in only a slight degree the system of following up cases after they leave institutions, with the purpose of keeping complete records of their lives and surroundings from the time of their appearance in the Clearing House. A study of such records will lead, it is hoped, to a knowledge of the causes of amentia, to the education of the public with regard to the vast number of these people in our communities, their special needs, the menace which they embody and the necessity for an intelligent consideration of the best way in which to meet the question of their care.

Consideration of the great number of these defectives would make it seem a heavy and expensive task to register and examine all of them, but if this is not done they sooner or later will prove an expense to the city through custodial care in institutions primarily maintained for other classes, such as prisons, reformatories, and hospitals. Moreover, never having been identified as mental defectives, many now are likely again and again to appear in various of these public institutions, whereas their first appearance before a city department might be made their final one if, on that occasion, their mental status was defined for all time by the primary examination in the Clearing House.

Present Staff.—Although the Clearing House had an official connection with the Department of Public Charities, it is now independent of that department, and is located as heretofore in the Post-Graduate Hospital. Over 7000 cases have been examined by the ten physicians attached to the staff. Only two of these were paid by the City of New York. The work done by the others is entirely voluntary. Should the volunteer physicians withdraw, the efficiency of the Clearing House would be so badly impaired that it would fail to satisfy the demands made upon it.

To cover the needs of New York City, such an institution should be equipped with a competent paid staff, consisting of at least ten assisting physicians, four psychologists, one chief examiner, eight stenographers, one filing clerk, one finger print expert, one statistician, three trained nurses and social investigators. Only by enlarging the staff in this way can New York City properly cope with the insistent problem of the mentally defective. Only in this generous way can the many departments of government and the auxiliary social agencies concerned, be assisted in their efforts to provide for those who because of mental defect have become a burden and a menace to society at large.

The intention of the director has been to have the Clearing House serve as an experiment for the city and State. The care of the feebleminded is not properly a local, and most assuredly not a private philanthropic matter; it must ultimately be borne entirely by the State. A chain of public psychopathic clinics should be established in the various population centers of New York State, and maintained as part of a State wide program for detection detention, training, and study of the mental defectives in the community. In order to make the work more uniform, and the results of greater social value, these clinics should be organized and directed by a State board to be appointed by the Governor. The members of this board, serving voluntarily, and representing all the various professions interested in this problem, could do much, aside from their supervision of these clinics, to advance the cause of social prophylaxis in mental defect.

In theory our program for the adequate care and ultimate control of feeblemindedness has long been known to the expert, and accepted generally by the public. In brief, we must care for our unfortunates in ungraded classes in the public schools, in special training schools, and in custodial asylums, depending entirely upon the degree of deficiency. This can be determined only after the most thorough medical, psychological, and social examination in a well equipped psychopathic clinic. We must also conduct scientific research into the etiological factors of amentia in laboratories to be established at all our public institutions.

All this must be done as part of a co-ordinated, unified attack on the whole problem, and must be made by the State authorities.

The greatest barrier to the furtherance of this programme has been the lack of co-operation on the part of the experts in the various fields of social effort that come into most intimate contact with the feebleminded, and should therefore work in the greatest harmony for their betterment. The present spirit of jealousy, personal ambition, and petty partisanship must give way to a large and more truly social spirit of co-operative effort toward the one purpose that is common to all—the public provision for the feebleminded, and the public prevention of feeblemindedness. In this we must all unite if we are to preserve and develop the mental stability and moral integrity of the American people.

Since the writing of this article the Department of Public Charities has withdrawn its help from the Clearing House for Mental Defectives. The Clearing House for Mental Defectives will continue, however, to do its work as heretofore at the Post-Graduate Hospital.

40 East Forty-first Street.

INDIVIDUALISM OR INSTITUTIONALISM.*

By C. N. B. Camac, M.D.,

New York.

What some of our graduates are doing.—I would like to speak first of some of those who have gone out from this school and who are taking their place as useful members of the community. Many of you know of the work being done by these various members of the alumnæ, but some of you may not, and I am sure our many guests here to-night are not familiar with the work of our graduates. The superintendent of Mount Sinai Hospital of this city is one of our graduates. The superintendent of Binghamton City Hospital, Binghamton, N. Y., is another. The superintendent of the Mount Vernon Hospital, New York, is also a graduate. Miss Jane Dindall, whom so many of you know, is superintendent of the University Hospital, Ann Arbor, Michigan. The superintendent of the Fairfield County Hospital, Fairfield, Iowa, comes from the City Hospital Training School. That is, there are five institutions whose hospital and training school are being conducted by graduates of this school.

In charge of the first division of the Canadian Military Corps of Nurses is Miss MacDonald, one of your alumnæ. This is her third war experience. In charge of the second division of the Canadian Military Reserve Corps of Nurses is Miss Ethel B. Ridley, a graduate and former superintendent of

*Address to the graduating class of the City Hospital Training School.

this school, well known to you all. This is her second war experience. These are the only two reserve corps which have been sent out thus far (October, 1914) by Canada, and they are both in charge of alumnæ of this school.

Two weeks ago (October, 1914) the Red Cross ship sailed from New York, with 100 nurses called "nursing sisters," and among these as chief nurse of the Brooklyn division was a graduate of this school. We had on that boat also another graduate of this school, and on the Greek boat, consisting of twelve nurses, was another graduate.

Two or three weeks ago I visited Montreal and Quebec. I took lunch at the Montreal General Hospital and discovered that so many of the internes had gone to the front that they had begun to draw on the American medical profession for internes. At Quebec I visited the Princess Patricia Camp, consisting of 11,000 men, and the Valcartier Camp, where there were 33,000. It was a wonderful sight, practically miles of tents in one of the most beautiful sections in the Province of Quebec. I visited the hospital of the latter camp, and while I confess to a thrill at this tremendous military display, which is unlike anything our generation knows, the thrill which I experienced was much deeper and more real as I saw the battalions of those serving in the Red Cross.

The medical division of the army.—In the medical division of the army there are no party lines, and no national lines. To build up and not to destroy is the main object of that group. Military history abounds with the names of those whose deeds fill us with admiration—men like Chinese Gordon, Hedly Vickers, and Stonewall Jackson, noble characters who rightly have a lasting fame, yet these widely-heralded heroes had especially the spirit of adventure and boldness, while in the medical division of the army there is, I think, also something of the spirit of the Master who came "not to destroy but to save men's lives."

Public recognition of medical services.—Governments are not prone to commemorate by statue or tablet the deeds of this army, fighting to prevent and rebuild the ravages of disease and war. There is in New York, with its many memorials, but one public statue to a member of our profession. In Boston the most conspicuous tribute to medicine is not to the discoverer, but to his discovery, anesthesia. This country on several occasions was terribly stricken by epidemics of yellow fever and cholera against which many men and women in the medical and nursing profession fought; yet not a single public statue exists to teach the lesson of self-sacrifice and devotion of this heroic army, many of whom gave their lives in the fight. In London Florence Nightingale this year only has received public recognition by a monument. This recognition would never have come, I believe, had not Miss Nightingale's first field of work been the military camp, which governments honor so freely. Jenner suffered mortification from a public discussion in Parliament over the question of whether his world-wide work in smallpox vaccination was worth £10,000 or £20,000. That the United States Government is erecting a building in Washington to commemorate the services of the nurses in the Civil War is a noble tribute, but here again it is war which has called out this recognition.

What of all those faithful, persevering lovers of truth who labor in the seclusion of the laboratory and hospital in the long unspectacular years of peace?

An essential quality in the nurse, the physician, and scientific worker is modesty and self-effacement. The greater the experience in this vast field of medicine the more modest and unobtrusive does the individual become, but it seems unfortunate that these lessons of self-sacrifice and perseverance equal to that of any soldier, sailor, or statesman should be so seldom taught by statue or memorial tablet.

A letter from the front.—If what I have said about our profession not having national lines seems to be an exaggeration, let me read to you a letter from one of your alumnæ—a letter written not from the front, but from the field of duty, a letter simple and full of such soldierly willingness to go and obey orders without murmur or self-consideration; a letter which expresses by its very simplicity, far more eloquently than I can, this spirit of—what shall I call it?—*service*. As you hear this letter, picture to yourself what I saw at Quebec—nine great ocean liners, the largest we know, ready to sail. Imagine yourself as a trained nurse waiting for orders to embark. The call comes and you go on board, cross the Atlantic, and in a day or so you are to land, and this is what you write home, possibly the last of your uncensored letters. Hereafter you will be permitted to send from the military camps printed post cards only, containing stereotyped news, which you will mark

On Board the "Red Cross"
Sept. 25th, 1914 (Nearing London)

My Dear .....

We are nearing our journey's end after a very pleasant trip. They promise that we shall come in sight of land this afternoon and probably land early to-morrow morning. Contrary to expectations, I am to land also, for last evening they made many changes in the units *and my turn came.* [Italics not in original.] Am now assigned to a unit bound for England. I have been thrown entirely with another group of nurses since coming on board and have not met any of the group for England, but I suppose we shall soon get to know each other. One other nurse goes along with me. One of my friends is still with the group for Germany, but I was told yesterday that both groups may be united. The Supervisor of this group is a most charming woman and I had hoped to be with her. Do not know my new supervisor, except by name.

The time on board has passed very, very quickly. They have held us down to classes a great deal of the time, more I think to keep us busy than for anything else, except the language classes. They have been very strenuous, but now our native tongue will be all I shall need—probably. There is still chance for another change though. One of our party goes to Russia, so will be with us until our arrival in London. I wonder what the next few days will bring forth and if there is the slightest chance of our still meeting in England. I still hope so.

Do you know where Miss ..... is? I know she is in some sisterhood over here and will undoubtedly be in the volunteer nursing work now. It would be wonderful to meet her.

Our mail is to be sent to U. S. Despatch Agency, 4 Trafalgar Sq., London, England, and if you know Miss .....'s address, do send it to me there.

The time here has passed so quickly it doesn't seem three weeks since I saw you. I wonder if there are changes with you.

Will send you cards as opportunity comes.

Yours very sincerely,

The simplicity of that letter speaks for itself: the willing soldier ready to take her orders to go in any direction and to receive changes and alterations in plans which she may have set her heart on. I wish it were more generally known how this

spirit actuates the large majority of your profession.

What is required of the trained nurse to-day?—I have told you of the work of some of those who have gone out from this school and now, may I speak to you, who are just leaving the school to begin your work? What does the field of nursing offer you to-day, or rather, what does it ask of you? There is a greater demand for the trained nurse to-day than at any time since the profession of trained nurse came into existence, because, added to the work of merely bedside nursing, are the many new fields of activity for members of your profession.

Over 1½ per cent., or nearly 2,000,000 people, of the population of the United States and Canada, succumbed to disease in a year—this does not include the great mass of non-fatal illnesses requiring careful nursing, nor does it include the vast number of accident and surgical cases, both fatal and non-fatal, and the confinement cases of which there were 2,000,000 last year in the United States and Canada. Compare these figures with the number of trained nurses in the United States and Canada, and it will be evident that there is abundance of work for the trained nurse, but that the laborers are few. Why, then, is it that the applications for the profession of trained nurse are so much fewer in recent years? Is the trained nurse underpaid? This question has been under discussion in many of your associations, but in dealing with the subject the same difficulty as that referred to in the matter of public recognition exists. It is hard to estimate in dollars and cents what trained nursing is worth to the public and the State. In business enterprises this would be estimated to a nicety, and the nurse would be paid accordingly. Business enterprises, having made such estimates, offer higher salaries to women and they are, in consequence, drawing women away from the vocation of trained nurse. While the salary of the trained nurse has not increased commensurately with the salaries paid by business pursuits, the demands upon her have increased far beyond that made by business.

The good women who followed Miss Nightingale did so with no other impulse than to care for the sick and suffering and with no training—she trained them. Hundreds of all classes flocked to this new occupation and few were incompetent. To-day you enter a highly cultivated field requiring individual efficiency and technical training. These high standards, together with the great increase of vocations for women, also explain why the number of applicants at the training schools has so greatly fallen off. Hospital and training school associations are discussing the nursing problem with regard to the "individual efficiency" of the nurse, her "preliminary training," and her early social and domestic influences. The medical profession is asking for nurses trained in operative and obstetrical work, in the care of contagious diseases, in pediatrics, in dietary and metabolism work, and the State is asking for those trained in municipal and social work, and the trades are employing nurses in the accident and preventive departments of factories and great industrial plants. It is only forty-four years since the first school of nursing was established in the United States. In 1880 there were only fifteen training schools, with 323 students. In 1911 there were 1048 schools, with 16,511 students. In 1911 there were 11,384 registered nurses in New York State alone. Such extraordinary development in so short a time in a practical country like this indicates the demand that has existed for the trained nurse and is evidence of the requirements which the future will make of your profession. All this means that your calling has become a highly technical profession, essential to the welfare of the community, and the woman who would succeed must select her line of work.

Setting aside now the large question of salary and trained nursing as a vocation for women, to which I have referred, I will speak of the problems which confront the graduate. Somewhat the same problems exist for the medical graduate and each of us must take stock of our capabilities, our early training, and social associations, in order to determine where our place is, but the trained nurse, especially, will meet either failure or spend many useless years finding out her mistakes if she enters her profession haphazardly.

It has been my observation that the heads of training schools do not sufficiently impress their pupils with the importance of this consideration of individual efficiency and fitness.

Fields of work for the trained nurse.—It is impossible in a brief space to consider all the openings for the trained nurse, but I would group them under the three following headings:

Philanthropical, under which come municipal work, social service work, district visiting, special clinic nursing, Red Cross, home nursing (not private nursing—see below).

Institutional, under which may be included heads of hospitals and training schools, heads of departments, heads of diet schools and kitchens, heads of operating rooms, hospital anesthetists (see below), heads of accident departments in stores and industrial plants; and finally,

Purely bedside nursing, including general nursing, surgical nursing, pediatrics, obstetrics, contagious diseases, neurological cases, mental cases.

I will refer in particular to two of these, as they are less familiar to most of us—home nursing and hospital anesthetists.

By home nursing is meant the care at their homes of hospital and dispensary patients. It is different from social service and district nursing work, although somewhat similar. Many clinics and hospitals have adopted this method of caring for patients. There is, of course, a salary connected with the work, but it requires a worker with a philanthropic spirit. It is now well organized in several cities, especially in Boston. In the American Hospital Association report for 1913 this work is fully described.

The work of hospital anesthetist has devoloped very rapidly in this country. In Germany, licensed physicians only are allowed to administer anesthetics and in France the internes are employed exclusively in the hospitals. In the United States certain States allow only licensed physicians to administer an anesthetic. About 14 to 25 per cent. of the hospitals in Canada and the United States employ nurses for this work. These nurses receive a salary of from $300 to $1,200 a year with maintenance. In the Mayo Clinic the nurse anesthetist has administered to over 10,000 patients. These nurses assist in the operating room and so gain additional experience. In the report of the American Hospital Association for 1911, Vol. XIII, this work is fully discussed.

At the City Registry, 52 East Thirty-fourth Street, New York City, under the charge of Miss Yocum, a graduate of this school, is a card index showing the institutions in need of workers and heads of departments, and also the names of those desiring such positions. There should be such bureaus throughout the country. I am told that this is the first of its kind.

The higher call.—Out of every class of graduates, it should be possible to group those suited for each class of work such as I have outlined. Those whose ambition is to follow the more specialized lines of work should be encouraged to pursue special studies. Many a nurse will, of course, find that she cannot afford to take more time for study; must get into active, remunerative work at once, but I am speaking now more especially to those who have heard the call and have proven themselves fitted for such work. To these I say, if the purpose is kept clearly in view and every period of slack business is used to further that purpose, the end will be gained. These obstacles confront the medical graduate also, but I have yet to see the man or woman of real worth, with set purpose, who is blocked permanently by this obstacle. Yes, there are those at home depending on you, or there is that brother or sister to educate—these are ennobling incentives to good work and to the keeping of your purpose to the front. Take all the cases you can get, send the money home—keep the purpose to the front—that sister or brother will finish the education and in turn will help you with the support of the home. The purpose has been kept to the front, and presently you will emerge fully equipped for your special work—appointment to it will come. To win out in a fight like this brings a sense of fitness and joy in work well worth the struggle.

I am certain that many of you have higher motives than the "qui bono," "what is there in it for me?" "What am I going to get out of this" spirit. I believe that in a body of young women or men starting on a career, there is a large percentage that hears the call, and longs to answer it. You are not looking for the easy money-making situation. You have had aroused in you during the early years and in those of training, desires to do something, to fill some place, and in acting upon this desire you have found abilities before latent—a sense of freedom, of power has come over you. *That is the Call*—and on the efficient, untiring answer to that call result the great deeds of heroism, of courage, of devotion, of progress, for the betterment of the world. The prosaic selfish side of our nature, and even members of our family will discount and ridicule these yearnings for up and doing—verily these latter "have their reward." Such people are the dull commonplace, whose only use is to test our perseverance. They must be resisted and left far behind. Stimulating and exhilarating as is this call, danger lies in the haphazard response. To hear the call is not to be fitted.

Institutionalism.—I have spoken of individualizing in the preparatory studies, but it applies also to our postgraduate work. I say "our" because we are of the same profession. A danger confronts us in these higher lines of work. This danger is best expressed by the term "Institutionalism." I think I can make this clear by citing two incidents. At Guy's Hospital in London, Dr. Bryant, a venerable pillar of that institution, was visiting the accident ward. He was standing at the far end of the ward, possibly in dreamy retrospect of the days when he was a young surgical interne. With him was a small group of admiring students. From the far end of the ward there came a dainty, mincing, young nurse, who approached the distinguished visitor (who, of course, was unknown to her) and said, "Take off your hat, please." This young woman was an excellent example of perfect institutionalism, with eyes for nothing but the ward sign, "Remove your hat."

Upon another occasion I visited a hospital on a mission of mercy. Full of an impulse to help the unfortunate patient whom I had come to see, I entered the office of the head nurse to inquire in which ward he was. A tall figure rose and, placing two fingers on the table, said, "What may I do for you?" It was as if a chill air had struck me. I explained my object and she replied, "Well, it's after visiting hours; anyhow, I think he died this morning." This is another example of "perfect institutionalism."

You laugh at these instances, but I assure you any one of us may develop this machine-like manner after several years of institution work.

There is an active campaign in many of our hospitals against this institutionalism, but it really depends upon each one of us whether we will allow institutionalism to steal away our human sympathy. Dr. Woelfkin has spoken very beautifully of this with regard to the attitude of nurse to patient. Many men and women think that acts of sympathy in an institution are evidence of foolish sentiment detrimental to efficient work. I think it is safe to say that the nurse who does not cultivate the sympathetic attitude toward all about her in an institution or in private work reduces her efficiency by at least 50 per cent.

Business to-day, keen for every point of advantage, places *manner* high in the scale of efficiency of the employee. The following instructions are taken from a printed list for the guidance of employees of one of our large railroads:

"Words are only one means of expression and manner is quite as important; therefore, remember that a kindly and gracious manner is not only the sign and mark of a self-respecting man, but it is to your words what oil is to machinery in making them more efficient to their purpose."

Over the gateway of the great Virchow Hospital is this inscription, "Treat the patient but don't forget the human being," which, I think, best expresses what I mean by "individualism" rather than "institutionalism."

But, I see here on the table a lot of diplomas to be given out, and furthermore I am mindful of the words of President Hadley of Yale, who, when asked by a speaker how long he should talk, replied, "That is at your discretion, but there is a tradition here that no soul is saved after twenty minutes." The hands of the clock are close to the salvation point, so, in the name of the Medical Board which I represent at this gathering, I wish you "godspeed."

128 East Sixtieth Street.

Medication by Inhalation.—G. Moretti has performed a series of experiments which show that the mucous membrane of the respiratory tract is capable of absorbing to an appreciable degree for therapeutic purposes drugs insufflated in the form of a dry powder, notably the iodides and compounds of calcium.—*Giornale Internazionale delle Scienze Mediche.*

MEDICAL AND SOCIOLOGICAL PROBLEMS OF DEPARTMENT STORES AND THEIR RELATION TO TUBERCULOSIS.*

By MORRIS H. KAHN, M.D.,

NEW YORK.

CHIEF OF CLINIC IN INTERNAL MEDICINE, MOUNT SINAI HOSPITAL DISPENSARY; ATTENDING PHYSICIAN TO TUBERCULOSIS CLINICS, DEPARTMENT OF HEALTH, NEW YORK CITY.

Published reports of the industrial improvements relative to the health and welfare of employees often betray unwarranted enthusiasm. Few at all comprehensive publications have appeared dealing with the activities and achievements of department stores in reformative directions. Some of these have been stigmatized as "misleading in many points" and no statistical or discoursive studies have been made with respect to tuberculosis as a department store problem. It may, therefore, not be amiss to study and compare the essential facts, as they are revealed by what records there may be, and to open a field which promises to be fruitful in benefits.

The existing conditions may be classified under the headings economical, social and sanitary; but these are more or less associated and include the many other still disputed questions. The subjects of hygienic conditions, average wages and hours of employment are gaining due publicity and their relation to the moral standards of the community is being recognized. Education, the public Ganymede, holds out the beacon, and promises to solve some of the problems of sanitary science. It finds its greatest obstacle in the conditions of labor and home life, created in the rapid development of the industrial revolution.

In considering changes for the improvement of the conditions of a community, whether from a sanitary or a social standpoint, it is reasonable primarily to acquaint oneself with the existing habits of the people, with respect to the necessaries of life, their home conditions, their sources of income, and in what measure the modes of their life and their occupations are unfavorable to their health. These have all been discussed with respect to the organized industries, but the motley crowd of unskilled employees of department stores have been passively waiting for the study which is but now on the wing. The economic conditions of department store employees are well known. In some families, where management is poor, or from which money is drained by sickness or intemperance, there is often indebtedness for food and other commodities. The more frugal or fortunate provide for a duller hour. The great proportion fluctuate between these limits, with the variations occasioned by sickness, seasonal unemployment, and those many domestic changes that may affect each household.

In speaking of department store employees as a class, it should be noted that salespeople form the great majority as compared with the office force, bookkeepers and stenographers who are trained for their work. An attempt has recently been made to organize schools in department stores, aiming to supply a more definite preparation, physical and mental, for salesmanship. But so far, the vocational schools seem to have added little to the happiness of the employees. And the reason is not far to seek. The vocational teacher is confronted with numerous individuals who have been forced into occupations they may not fit. They take up the task which offers itself first, though their natural inclination may be toward something different or as yet uncertain. As a result, many industrial misfits are cultivated, discordant with and unadjusted to the work they pursue. It is in our formative years that our industrial ideal may be recognized and the so-called motive of our life-career should be discovered and brought into play as early as possible. Typical of this conception is the early autobiography of Benjamin Franklin, who says: "He (my father) therefore sometimes took me to walk with him and see joiners, bricklayers, turners, braziers, etc., at their work, that he might observe any inclination and endeavor to fix it on some trade or other on land." The individual would thus manifest his search for individuality with greatest success in the best permanent occupation for which he is capable. But instead of such an evolving process, some phases of vocational training convert it into a mechanical hammering process, which moulds people into positions unsuited to their ability and uncreative of their happiness. And it is the independent opinion of a number of observers that many thus employed devote very little time to abstract thought. They look no further than the immediate future. Ignorance is their opiate. They suffer, but they know it not. They attribute their ills to the iniquity of God, instead of directing their own endeavors toward bettering their own conditions. Ignorance and inefficiency are the two aspects of such conditions, which while self-accusing, form their own defense. A machine that does not fulfill the purpose for which it was constructed may be said to be inefficient; and by a metaphor, a man may be charged with inefficiency or ignorance only after he has been educated or trained for his work. Otherwise, his excuse lies in those social conditions which confined his childhood to the stuffy, stagnant air of overcrowded homes and commanded him to spend his early years in seeking self-support.

In studying the social needs of employees as a body, the department store administrator is confronted by the inevitable fact that but a very small proportion of the working day can be devoted to pleasure. Recreation-rooms on an enclosed roof, soft-armed chairs, music and books may all be provided to beguile the fleeting hours. These are good signs of the times. But in reality the fleeting hours crawl behind the counter. The value of such recreation is, however, not to be denied. It serves as a stimulating break in the monotony of routine and an incentive to the expression of those regrets which many of us have heard made by employees on their having to return to work. It also fosters the desire for education and gives the employees the taste for the conveniences and comforts of life, with a resulting desire for bettering their condition, which has been happily called "the mainspring of public prosperity." The atmosphere of ease in some stores is taken advantage of by serving a lecture on hygiene as the last course of their midday meal, and there is reported manifest interest in health topics.

The welfare service, as it is called, is a needed part of the social work. One or more intelligent girls, preferably nurses, visit the families of needy employees and investigate conditions chiefly investigate conditions. They then provide immediate relief, as food, clothing, or coal, when necessary, and then they study the case comprehensively with a

* Read at the meeting of the Association of Physicians Attending the Tuberculosis Clinics of New York City, April 14, 1915.

view to ascertaining the fundamental need of the family, and treating the cause of the trouble as best may be done. This work is carried on along the lines set down by the organized charities. Another institution maintained by department stores without profit is the loan fund for employees, which protects them against the usury of unconscionable individuals.

But almost all social service in the industries is merely an apology. It is like the bone pacifying the animal which it cannot satisfy. It may temporarily ameliorate conditions, but there is often a vicious circle which creates and maintains the conditions calling for correction. However, as the basic causes seem invincible, and do not easily permit of being assailed, what is being done is commendable in a high degree. But it must be conceded that it does not strike at the root of the existing evils.

Prevention of disease by sanitary measures and early recognition of disease are the great aims of medical supervision. In the several industries the physician is on the premises for a varying number of hours during the day and examines and treats the medical and minor surgical cases. When found ill and with fever the cases are sent home and instructed to stay in bed. Throat cultures are taken in all suspicious cases. Exact treatment is outlined until the following morning and the patient is advised when able to consult the family physician. If the patients are better the following morning and return to work they are seen then. If still ill they report the fact, after which they are visited and advised according to their need. When necessary, the patient is referred to the proper hospital and arrangements are made for admission. Cases requiring dispensary care, as for test-meals, *x*-ray examinations, etc., are sent to the proper clinics. One store has granted leaves of absence for this purpose to employees on pass from the physician, without deducting the time.

During the past several years some industries, department stores also, and municipal departments have undertaken a method of medical supervision which calls for periodical physical examinations of every individual in their employ. These are not compulsory. In insurance companies and other large corporations where the plan has been tried good results are reported. In many department stores there is still a general lack of appreciation among the employees of the advisability and need of a personal physical examination about once each year. Through such routine studies, cases of unsuspected kidney-disease, heart-disease and diabetes have been discovered, and cases of pulmonary tuberculosis. It is natural, however, that employees should hesitate to undergo a physical examination by the physician supplied by the industry. There is certainly apprehension in the minds of the workers, as has been expressed by one of their representatives, that as soon as their illness or their deficiency is ascertained they will be discharged, with prospects of an ensuing idleness, which will aggravate their situation and condition.

But education is a weapon that can with safety be placed into the minds of every individual. "The only cure for public distress is public education." It is evident that no great progress can be made in disease prevention or in any other reform without education. Individual progress is characterized by accumulation of knowledge, just as social progress is by its diffusion. One follows the other inevitably. That is to say, when one person makes a step forward intellectually the whole world advances to the tune. A visionary might look forward and contemplate the distant time, when each individual may be self-sufficient: just, wise, and healthy, his own doctor and his own counsellor.

This is a far cry from the present. Several principles may be outlined along which certain medical conditions in department stores can be dealt with. One principle asserts the transfer of employees from one kind of occupation to another more fitting their state of health. This is particularly serviceable in department stores, because of the variety of work available. The employees are moved about so that with regard to their infirmity, they are the better adapted to their work; and what might have caused harm for them is converted into benefit. In cases of heart-disease an unskilled girl, working at a busy counter, for example, may be put at rest as a cashier. So also with rheumatic individuals working on the more or less wet floor behind a soda fountain. Again, members of tuberculous families, or individuals showing a predisposition to tuberculosis, can be transferred from indoor to outdoor occupations. These changes, it may be remarked, should not involve a reduction of wages, which would detract from the benefit derived by the mental worry ensuing.

The occupational diseases deserve a passing mention. As has been stated, department store labor comprises no unity of employment. The proportion of employees engaged in obviously injurious occupations is necessarily small. Probably the one consideration of significance from this standpoint would be the dust of especially the packing and delivery departments. Salespeople may also be exposed to fiber dust, but though few are the occupations in which dust is not given off, in none can it be absolutely harmless. However, no morbidity statistics can be compiled because of the unstationary and fluctuating mass of people employed.

Pulmonary tuberculosis occurs in a sufficient number of department store employees to demand consideration. Very little concern has been given to this subject that presents such an importance. One department store in New York City revealed twenty-four cases of pulmonary tuberculosis, with physical signs in the first thousand consecutive examinations, and another store showed about the same proportion, with four cases of advanced tuberculosis with positive sputa in the first two hundred and fifty cases examined, and a number of suspected incipient cases besides. No other statistical data on this subject are to be found. All department stores, and many other industries as well, have great difficulty in properly disposing of their tuberculous employees. It is a universal practice of these institutions, necessary and apparently just, to exclude from employment cases of pulmonary tuberculosis that are a menace to the community. Yet this is often disastrous for the employee and his family and may cause domestic havoc. By excluding a tuberculous employee, not only does he become in many cases a charge upon the community, but the family is deprived often of its only source of income. Sometimes the tuberculous case is sent to a sanitarium or municipal hospital. Frequently this means the disruption of the family, the mother assuming the support of children who are kept in a day nursery or scattered among strangers. A tribute is to be paid by department stores to Stony Wold and other sanatoria, which have taken

care of a number of cases referred to. But for the larger number the benefits of sanatorium treatment are often unavailable on account of cost, insufficient capacity of the existing institutions, and the too brief period of time the patient is permitted to remain in them. And when sanatorium treatment is possible, the lesson learned is of no permanent benefit, if upon discharge from the sanatorium, they are returned to the unfavorable living conditions which contributed to cause the disease.

The idea of the Home Hospital, if generalized, would promise greatly as a solution of the problem. The dwelling places of most of the employees lack both fundamental principles expressed by the name. Many can scarcely be called a home, and much less a hospital. The old housing problem seems to have a long youth. The vivid description given of tenement house life by Dr. Armstrong and Commissioner Kingsbury would allow of but one suggestion—*that the principle of slaughter, with or without compensation, as used in the management of tuberculous cattle, be applied to the treatment of tuberculous tenements.* The analogy lends itself further. The following quotation from the report of the International Commission on the Control of Bovine Tuberculosis needs no annotation. "In the eradication of tuberculosis, it should be kept in mind, that, in addition to protecting animals against exposure to tubercle bacilli, it is desirable to make them as resistant to infection as possible. This can be done by stabling them in clean, disinfected and properly ventilated and lighted barns, giving them abundant clean water and nutritious food, a sufficient amount of daily exercise in the open air, and attending generally to those conditions which are well known to contribute to the health of animals. Young stock particularly should be raised as hardy as possible, and should be accustomed to liberal exercise and living in the open."

At a meeting of the Industrial League of New York, about a year ago, I had the privilege to recommend and urge the co-operation among employers in establishing a special sanatorium for workers who develop incipient tuberculosis. It would be practicable for department stores to join in a movement so beneficial to themselves and the community. Dr. Lee Frankel, Dr. Winthrop Talbot, Dr. George M. Price, and others present expressed favorable opinions with the hope, as Dr. Alfred Meyer said at the dedication of the McGregor Sanatorium, "that this kernel may grow to great porportions." And in his recent report to the Joint Board of Sanitary Control, Dr. Price has incorporated this idea, prophesying that "the time is not far distant when the enlightened members of the industry will be confronted with the necessity of co-operating with the workers' unions to establish their own tuberculosis sanatorium." The home hospital plan, that is, the building of habitable houses, permitting of an abundance of fresh air and sunlight, deserves great consideration in such a movement. In the department store cases, the tuberculosis and the poverty are more or less incipient, and the dependency is very often due to the disease of the wageearner. The family must be conserved for the welfare of the household.

I believe the seed has takn root at length. Two members of the Retail Dry Goods Association of New York have pledged their material support of the idea, and their secretary recently informed me that "the matter of establishing a sanatorium for tuberculous employees was discussed, but laid over until one store is in a position to decide certain points in connection with this matter." Some department store employers may object to being thus saddled with another burden. But, in reality, it has already been found that sanatoria of the character of the East River Homes Foundation pay for themselves. Besides, when established and maintained by many department stores, it would mean no greater expense for each than the present expense of each in expressing its moral obligation toward those employees who inherit tuberculosis as a legacy from their work. It is to be hoped that the physicians of all industries will see the need and study the practicability of such a cooperative measure.

165 West Seventy-first Street.

A CASE OF COMBINED EXTRACRANIAL PARALYSIS OF CEREBRAL NERVES.

By JOSEPH C. BECK, M.D.,

AND

G. B. HASSIN, M.D.,

CHICAGO.

ATTENDING PHYSICIANS, COOK COUNTY HOSPITAL.

Combined lesions of cerebral nerves occur quite frequently, being usually due to some *intracranial* causes, as syphilitic meningitis or brain tumors, especially of the cerebellopontine angle. The *extracranial* occurrence of combined paralysis of cerebral nerves is exceedingly rare, much rarer than that of spinal nerves, as is the case, for instance, in brachial plexus paralysis of Erb, etc. The reason for the extreme rarity of extracranial combined nerve paralysis is probably the fact that the cerebral nerves do not form plexuses in the sense the spinal nerves do, the only exception being the IX, X and XI nerves which are massed underneath the jugular foramen in one bundle, forming, as it were, a plexus. Any pathological cause, a tumor, for instance, is liable to affect this mass of cerebral nerves and cause their paralysis. A possibility of such a lesion was pointed out by Oppenheim,[1] Bernhardt,[2] Unverricht,[3] and Flesh,[4] but a careful perusal of the literature did not reveal a single fact of a unilateral lesion of the above named nerves, outside the skull, caused by a tumor. This, however, was the case in our patient.

Miss McC., aged 18 years, consulted one of us (Beck) about two years ago for continuous pain in the neck, face, and forehead, and for difficulties in deglutition and speech. At the age of three she had measles and diphtheria; when six years old, tuberculosis of the cervical glands for which she underwent an operation. At the age of thirteen torticollis developed on the right side. Two years later she had continuous pain over the left side of the neck, radiating to the occipital region, and to the left side of the head. A year later impairment of speech was noticed, and the voice became rather hoarse and nasal, while the deglutition troubles were getting worse, solid food she could swallow with difficulty and fluids regurgitated. The speech and deglutition troubles and also the pain in the neck were getting worse during the following months, and the examination of the patient in October, 1913, revealed the condition as follows:

A well nourished young girl, physically and mentally well developed. Her speech was very unintelligible, disarthric, and with a nasal twang. The voice was slightly hoarse, interrupted by a stridor-like breathing. Along the left side of the lower jaw there was a scar 5 inches long caused by a previous operation (Fig. 1). The muscular and bony systems showed

no abnormalities, except the left sternocleidomastoid and the upper portion of the trapezious muscles which appeared rather atrophied. Passive and active movements, as well as the muscle power, were normal. The gait showed no abnormalities. Romberg was absent. The tendon reflexes very brisk, without clonuses,

Fig. 1.—Scar and incision.

Babinski, or Oppenheim. The skin reflexes, as abdominal and plantar, were normal. Pupillary reflexes, the mucous reflexes, except pharyngeal, the bladder, and rectal reflexes showed no abnormalities. The sensibility was not impaired. The cerebral nerves showed a rotatory nystagmus upon looking to the extreme right or left, but there was no nystagmus during the quiet position of the eyeballs.

The first seven cerebral nerves, including the eye grounds, disclosed nothing abnormal, but the eighth, ninth, tenth, eleventh, and twelfth cerebral nerves showed various disorders on the left side. Thus, the patient was totally deaf on both ears, which deafness was due to a bilateral otosclerosis. The lesion of the left ninth and tenth nerves was evidenced by a paralysis of the left half of the soft palate and uvula which was deviated to the right; by great diminution of the pharyngeal reflex and paralysis of the left vocal cord. The taste was not impaired. The pulse was 144, which also probably spoke for an involvement of the tenth nerve. The eleventh nerve paralysis was represented by deviation of the head toward the right, by the atrophic degenerative condition of the left sternocleidomastoid and of the upper portion of the trapezious muscles. The lesion of the left twelfth nerve was shown by a left hemiatrophy of the tongue (Fig. 2) with marked fibrillary twitchings. The left half of the tongue appeared soft, spongy, and covered with deep furrows. When protruded the tongue deviated to the left. The subjective complaints were an indistinct dysarthric nasal speech, hoarseness, slight difficulty in breathing which was stridor like, difficulty in swallowing with regurgitation of fluids, and some difficulty in moving the head to the left and keeping it straight. These symptoms could very well be explained by the lesion of the ninth, tenth, eleventh, and twelfth nerves. In addition there was, as mentioned, a nystagmus, upon looking to the extreme right or left.

The above named nerves all were involved on the left side, and the question arose what could be the cause of this combined nerve lesion. The history showed that the patient had been suffering from enlarged cervical glands, tuberculous in origin, for which she was once operated upon. It was proper to assume that one of these glands affected all these nerves somewhere where they are massed together, such a place being the jugular foramen. Passing the latter, the ninth, tenth, and eleventh cerebral nerves are joined by the twelfth and it was concluded that all these four nerves were compressed by a tumor which probably was a tuberculous gland. An *x*-ray showed a calcareous mass in the indicated place (Fig. 3) and an operation was decided upon.

Four weeks later operation was performed. An incision was made from the mastoid tip to the level of the cricoid cartilage along the sternocleidomastoid. The hypoglossal vagus, spinal accessory and superficial cervical nerves were dissected particularly upward to the base of the skull with exposure of large vessels. A calcareous gland with a number of smaller infiltrated glands were dissected from the nerves and jugular vein, each nerve being surrounded with Cargile membrane, and the wound closing by primary intention. We must mention here that the tuberculin test was slightly positive, while the blood, urine, and spinal fluid serologically and otherwise proved frankly negative, all these examinations having been done before the operation.

The patient showed marked and progressive improvement. Thus, the pain disappeared almost immediately after the operation, and the rest of the symptoms were gradually, though slowly, subsiding. When examined six months after the operation, there was noticed marked improvement in the shape of the tongue. The atrophy was almost gone but the fibrillary twitchings were still present. The soft palate and the uvula were normal and deglutition troubles, as well as difficulties in breathing and speech, were absent. The reflexes, sensibility, and other findings were the same as before the operation. The eye grounds were normal, there was no tremor and the nystagmus was very slight, in the form of slow rotatory movements during movements of the eyeballs to the extreme right or left. The mental and the general physical conditions were excellent. The patient, in fact, did not complain of anything and was happy and eager to do housework. The pulse was 96 as against 144 before the operation. The patient's condition was the same a year after the operation, being thus stationary. The slow disappearance of the anatomical changes was ascribed to the slow regeneration of the nerves involved and to the possible formation of adhesions. This is the more possible, as there was no further marked improvement since the patient was seen last, about one month ago, i.e., sixteen months after the operation, yet the general and

Fig. 2.—Hemiatrophy of the tongue.

local symptoms were found to be considerably better than before the operation and the improvement of so long a duration must be attributed to the release of the ninth, tenth, eleventh, and twelfth nerves from pressure in the vicinity of the left jugular foramen by enlarged and infiltrated cervical glands.

Analyzing this case, we wish to call attention to the following features: (1) Pain in the neck, occiput and forehead. (2) Marked hemiatrophy of the tongue. (3) A combination of the tongue atrophy with paralysis of the ninth, tenth, and eleventh cerebral nerves. (4) Nystagmus. The pain in the neck, occiput, and head was, in our opinion, due to pressure on superficial branches of the cervical plexus (occipital nerves, great auricular nerve), to vascular disorders in the cerebral sinuses (inferior and superior petrosal, cavernous) also probably caused by pressure on the jugular vein with possible vascular disturbances in the gasserian ganglion, as the result of the sinus troubles. The hemiatrophy of the tongue was the object of numerous discussions in the literature. Thus, Ballet,[5] claimed that it almost exclusively occurs in tabes, being exceptionally rare in any other disease. Ballet's contention was combated by Marie and Koch,[6] who showed that hemiatrophy of the tongue also may occur in brain syphilis, paralytic dementia; and by Hirt,[7] in whose patient it was probably caused by a bulbar hemorrhage. Our case also proves that lingual hemiatrophy may occur in diseases that have nothing to do with

FIG. 3.—Calcareous lymphatic gland

tabes. A combination of the tongue hemiatrophy with paralysis of other cerebral nerves has been repeatedly described. We shall mention Fränkel,[7] Hirt,[8] Jackson,[9] Remak,[10] Unverricht,[11] Pel,[12] and Debove.[13] In Fränkel's patient there were symptoms similar to those in our patient, but in addition also some symptoms on the part of the sympathetic nervous system, as contraction of the left pupil with preserved reaction to light, but normal palpebral fissure; right exophthalmos; and severe pain. The cause was a tumor of the right cervical region (lymphosarcoma) involving the superior sympathetic ganglion. As Bernhardt[2] reports, Fränkel had to change the diagnosis to that of tuberculosis of the base of the skull and of the cervical glands.

Jackson's patient, a syphilitic, showed right hemiatrophy and paralysis of the tongue, of the right half of the soft palate, of the right vocal cord, *i. e.* the same symptoms as in our patient, but there was also present a degenerative atrophic paralysis of the muscles supplied by the brachial plexus. There also was a left Argyll-Robertson pupil and sweating of the left side of the face. Mackenzie, discussing Jackson's case, spoke of eight cases of unilateral paralysis of the tongue, soft palate, and vocal cords. He thinks that such a combined nerve paralysis was due to a lesion of the vagoaccessory nucleus, but adds that it could also be caused by some extramedullary morbid process. In two cases he could demonstrate the involvement of the sternocleidomastoid and trapezious muscles. In one case the paralysis of the tongue, palate, and vocal cord came on, like in our patient, coincidently with the paralysis of the sternocleidomastoid and trapezius muscles, but he did not know if a bulbar lesion could cause such a coincidence. Mackenzie's two patients bear a striking resemblance to our case but the etiology in his patients remained obscure. In Hirt's patient who was 76 years old there was a sudden paralysis of the right half of the tongue and right vocal cord with a lost pharyngeal reflex, which lesions followed an apoplectic stroke. Hirt thinks that there was a bulbar hemorrhage with embolic softening of the vagohypoglossus nucleus. Remak's patient had a bilateral paralysis of the posterior cricoarytenoid muscle and of the right half of the soft palate and uvula; right hemiatrophy of the tongue, combined with left ptosis; Argyll-Robertson pupil, and paralysis of the left arm and right thenar atrophy. Remak excludes tabes (?) and diagnoses lead poisoning. In another patient Remak[14] found paralysis of the right vocal cord, soft palate, and tongue, with fibrillary twitchings; difficulty in deglutition; paralysis of the right side of uvula; deafness of the right ear (four-five years standing); and atrophy of the right sternocleidomastoid and of the clavicular portion of the trapezius. These symptoms, so similar to those in our patient, were combined with twitchings in the right cheek, followed by seventh nerve degenerative paralysis. There were also present nystagmus and Argyll-Robertson pupil, the tendon reflexes having been normal. Remak could not make a positive diagnosis but excluded tabes in spite of the Argyll-Robertson pupil (?). In Unverricht's case, a sarcoma of the base of the brain, all the cerebral nerves became rapidly paralyzed, and he ascribed the paralysis of the ninth, eleventh, and twelfth to pressure in the jugular foramen. Pel's patient complained, like our patient, of pain and stiffness in the neck and occipital region, and showed atrophy of the left sternocleidomastoid and trapezius muscles, a left vocal cord paralysis, left hemiatrophy of the tongue, and paralysis of the left side of the soft palate and uvula. There were nasal speech and deglutition troubles with regurgitation of fluids. To complete the analogy with our case, there was enlargement (universal) of the glands but the patellar reflexes were lost. Pel rightly concludes that he had to deal with a peripheral lesion of the ninth, tenth, eleventh, and twelfth nerves, "an einer Stelle, wo die Nerven von der vena jugularis getrent werden," yet he excludes a peripheral lesion, because he says circulatory disorders, the reaction of degeneration and the entire (?) involvement of the eleventh nerve were absent. He also excludes any basilar lesion, and diagnoses possible tabes with endarteritis of single branches of the left vertebral artery, which carry the blood supply to the nuclei of the hypoglossus and vagoaccessory nerves. Finally Debove's case must be mentioned. In this the left ninth, tenth, and twelfth nerves were injured, together with the left sympathetic, during an operation on the neck for an epithelioma. The left

carotid was ligated, and the clinical symptoms caused by a lesion of the above named and sympathetic nerves, as hemiatrophy of the tongue, paralysis of the left vocal cord, hoarseness, miosis, and enlargement of the palpebral fissure, were followed by a right hemiplegia and aphasia 24 hours after the carotid had been ligated.

There have been numerous other cases reported of combined lesion of the cerebral nerves, by Avellis,[15] Dinkler,[16] Rothman,[17] Rose,[18] Léjonne and Oppert,[19] Foix,[20] but the majority of these cases were either due to intracranial tumors (Dinkler), syphilitic meningitis, or unknown causes (Avellis), thus differing clinically from our patient and from the cases quoted above. The cited cases also show how difficult it was to interpret them and to properly diagnose and treat them. These cases also show that in none of them were the ninth, tenth, eleventh, and twelfth nerves exclusively involved by an extracranial tumor (except possibly Pel's case) which continually pressing upon these nerves caused their paralysis and degeneration.

In conclusion we would like to touch briefly upon the last peculiarity of our case, the involvement of the eighth nerve and nystagmus. The eighth nerve involvement was bilateral, as the patient was completely deaf on both ears, and the deafness was due to otosclerosis. The latter seems to be a family trouble, as the patient's mother and two sisters suffer from deafness due to the same pathological cause. The nystagmus was marked only during active movements of the eyeballs, and during the last sixteen months became quite peculiar, showing slow oscillatory movements toward the left or right, according to the direction of the intentional movements of the eyes, without the quick return to the opposite, this slow deviation being, according to Wilson and Pike,[21] the only essential movement of a socalled labyrinthine nystagmus. The question arises if the labyrinthine trouble of our patient, the otosclerosis, could not cause the nystagmus, which is thus most probably of vestibular origin. At any rate, the nystagmus and deafness are in our patient essentially different and independent lesions, having nothing to do with the principal affection our patient suffered from, namely, tuberculosis of the cervical glands with secondary involvement of the ninth, tenth, eleventh, and twelfth nerves in their extracranial course. Such a diagnosis was not only verified by the *x*-ray examination, a successful operation, but also by the subsequent progressive improvement. The latter cannot be looked upon as a remission of some brain lesion proper, multiple sclerosis, for instance, which was diagnosed in this case by a competent neurologist, but must be ascribed to the removal of the cause, which was a tumor in the form of an enlarged infiltrated cervical gland.

NOTE.—A few months after the date of the above report the patient began to show a recurrence of the symptoms of pressure on these nerves and another operation for the exposure of them was decided upon by us. On July 5, 1915, the operation was performed and the nerves were found surrounded by dense fibrous tissue. The hypoglossal, spinal accessory, and vagus nerves were again dissected up as far as the jugular foramen (the internal jugular vein was wounded in the dissection). Recovery from the operation was uneventful and the marked improvement in the voice and tongue showed again that our diagnosis was correct. The progosis however is certainly unfavorable since secondary scar formation and contraction over the nerves cannot be prevented.

A STUDY OF THE OCCURRENCE OF DIPHTHERIA BACILLI IN NORMAL THROATS.

BY ROBERT A. KEILTY, M.D.,
PHILADELPHIA.

(From the McManes Laboratory of Pathology, University of Pennsylvania.)

THE purpose of this paper is the determination of the number of virulent diphtheria bacilli in normal adult throats.

During my experience as medical inspector in the Bureau of Health of Philadelphia the occurrence of positive cultures of Klebs-Loeffler bacilli in apparently perfectly healthy throats, of both adults and children, was astonishingly frequent. This was especially apparent in children. The district to which I was assigned covered a large mixed population mostly of the poorer classes. While crowding was not a feature, the houses were mostly damp, having been built to a large extent upon "fill-in" ground.

The frequency of positive cultures in normal throats eventually led me to disregard the cultural findings entirely in a diagnosis of diphtheria. This seemed to me to be a serious state since so many men rely upon the culture to settle a doubtful case. The principle which I came to follow was that it was better to give 100 cases of tonsillitis antitoxin than to withhold it from one true case of diphtheria.

*Read before the Philadelphia Pathological Society, June 10, 1915.

From a practical standpoint this plan worked out very satisfactorily. Anyone who has had any considerable experience must admit that the doubtful case turns up every once in a while, diminishing in frequency as his experience increases, but never becoming an entirely negligible factor.

Because of this experience, which I am sure must be the experience of many others, especially those working on health boards, I determined to examine the throats of 100 students whom I knew to be free from exposure, to have sanitary housing conditions, and to be generally in good physical condition. I had fully made up my mind to find not a high but a moderate percentage of positives.

The technique was as follows: Swabs were made by carefully going over the entire tonsil on both sides without contamination from the tongue or other parts. These were well drawn over blood-serum slants and dipped in the water of condensation. The tubes were incubated at 37° C. for 24 to 48 hours. Smears were made from the slants and from the water of condensation and stained with Unna's methylene blue. All cultures containing suspicious-looking rods were plated out on plain agar-agar, blood serum, or in some instances both. These plate cultures were examined from their gross and microscopical characteristics and where still suspicious the throats were recultured.

The results: Ninety-seven cases were examined over a period of two years, 50 in one class and 47 in another. Of these 21 cases had suspicious rods. By this I mean any rod which morphologically resembled the Klebs-Loeffler bacillus. In no case were they perfectly typical and in no case did they occur in more than a few colonies. Of these four cases were replated and recultured. But one of these was considered likely and this was injected into a 750-gram guinea pig. A slight local reaction resulted and the pig was alive at the end of five days. This was considered a negative result and the type a pseudodiphtheria bacillus.

Recent literature does not contain many similar reports, but those recorded generally agree with this result. The percentage of positives in adults varies from 0 to 2. In children this is a great deal higher, up to 25 per cent.

Conclusions:

1. The percentage of occurrence of Klebs-Loeffler bacilli in healthy normal adult throats under hygienic conditions is low or nihil.

2. A positive culture with suspicious membrane in this class of cases should have a great deal of weight.

3. Granting this positive evidence of value I am still inclined to believe that cultures play altogether too large a part in the routine handling of diphtheria.

I am indebted to Mr. J. A. Magoun and Mr. Charles E. Behney for assistance in the technical work.

A FURTHER REPORT UPON THE ETIOLOGY OF PELLAGRA.

By DUANE MEREDITH, M.D.,
WICHITA FALLS, TEXAS.
FORMERLY ASSISTANT PROFESSOR OF BACTERIOLOGY, FORT WORTH UNIVERSITY.

In presenting this paper I realize that I am claiming to have accomplished what better men have failed to do, men who are not only better trained than I am, but have given their entire lives to the study of this disease; who have examined hundreds of cases to my one, who have made careful post-mortem examinations where I have been denied that privilege. But, with all these facts staring me in the face, I still believe I have a message that will be worth a great deal not only to the medical profession, but to the human race in general.

I shall limit my paper to the etiology of pellagra and what I take to be the causive factor of this disease. I shall first give a list of the different theories of this disease, quoting from a report of the United States Public Health Service (Bulletin No. 48) on pellagra, prepared by Dr. C. H. Lavender. While this report is three years old, it is the best thing that I have been able to find upon the subject.

That corn had something to do with this disease was first advanced by Gaspar Casal, in about 1735. That corn was responsible was taught by Marzari, the founder of Zeist school, in 1810. He believed that corn was lacking in some of its nutritive properties. Balardini believed it to be due to the use of damaged or fermented corn. Later Lombroso devoted many years of his life to the development and defense of this theory as the cause of pellagra. Other workers of this school believed it to be due to certain mold upon corn. Various others believed it to be due to some specific organism. Pari incriminated the maize smut, Majocchi and Cuboni the *Bacillus maydis*. Carrorriola described a *Bacillus pellagræ*. In 1902, Ceni thought the *Aspergillus fumigatus* and *A. flavescens* were causes. His work, however, has not been confirmed. In 1906 Tizzoni described a streptobacillus. This micro-organism he found in spoiled corn, the blood, spinal fluid, and certain tissues of pellagrins. His work lacks confirmation.

Sambon in 1905 advanced the idea that it was due to some parasite and was transmitted through the bite of some blood-sucking insect. He thinks it is some species of the buffalo gnat; as to the causive factor he advanced no theory. Alessandrini believes it to be caused by a water-borne nematode worm; others believe it to be caused by the action of cottonseed oil through some of its end products. Dr. C. H. Harris of New Orleans has shown that it belongs to the filterable viruses. He was able to pass the spinal fluid through a Berkefeld filter, and by inoculating a monkey obtain typical lesions. There has been no one able to get his work confirmed up to the present time from theories advanced.

This brief review of theories that have been advanced by various workers on this disease, I do not think has been in vain; as my work in a great measure will tend to show that both factions are partly right. I shall first give a brief history of my work upon this disease, later describe the morphology of the organism, and lastly give the statistics that I have collected which will tend to show that this disease is infectious and is transmitted through some infected insect.

My preliminary report of this work was published in the *Texas State Medical Journal* of October, 1913, in which I reported how I had obtained an organism from the blood culture of a pellagrin suffering from a high temperature at that time, and had been able to grow this organism, and at that particular time thought that I had succeeded in infecting a chicken by intraperitoneal inoculation; the comb peeled off some six weeks later, and after cool weather set in, the chicken apparently got well.

In the latter part of January I had a patient

come to me suffering from a bullous pellagra lesion on the back of both hands. I made a culture from them, from which I obtained typical growth. I also made smears from which I was able to stain a typical organism. In these smears I would often find small organisms looking a great deal like spirilla. I had seen this in culture tube smears. In March I conceived the idea that one ought to be able to make a fixation test from a proper antigen so I grew several tubes and prepared an antigen. Six weeks later I made a fixation test from three different male pellagrins, all of which were strongly positive, no hemolytic action taking place after several hours.

On May 30 my chicken died; at that time he was over a year old and should have weighed two or three pounds; instead he weighed only half a pound, and I never saw anything so near a skeleton. Being very busy, I did not have time to make a careful post-mortem, so I took a sterile knife, removed the bone from the top of its head, inserted a sterile hypodermic syringe (all glass with a platinum needle) down to the base of the brain. I was able to obtain about one c.c. of fluid which I planted out in three separate tubes. I had two positive cultures with typical growth; I also made smears and was able to obtain the organism by staining. The chicken began to develop lesions some six weeks prior to its death and became very nervous before expiring. From the character and size of the spores I thought the organism belonged to the filterable virus class of organism, so after sterilizing, I filtered one of my cultures through a Berkefeld filter with the aid of a water suction pump. The filtrates I centrifuged for fifteen minutes, then made plantings on moist blood serum, and got typical organisms in each tube.

In June I had a pellagrin with one of the most severe cases of cystitis that I have ever seen, not excepting a carcinoma of trigone. Her doctor sent her to me for stone in the kidney, but after *x*-ray, uranalysis and cystoscopic examinations, white blood, and differential leucocyte counts, together with a history of extreme nervous symptoms, sore mouth, and vague, indefinite pains of great severity, I made a diagnosis of pellagra. She had a pain on the left side at the lower border of the ribs, and as this has occurred in every case of pellagra that I have treated, and does not occur so far as I know in any other disease, it always makes me think of pellagra. She was running some temperature and having a chill every few hours. I tried to get some blood from the median cephalic vein to make a fixation test, but the vein being small I succeeded in getting only about one c.c. that I planted out, getting a typical growth from which I was able to get the organism, confirming my previous diagnosis.

On September 20 I inoculated a Rhesus monkey subcutaneously with one c.c. of blood serum cultures. For the first month he lost weight and grew nervous and lost his appetite. He had a marked increase in the pigment of his hands and face, which became nearly black, while his control remained normal in every respect. At the present time this discoloration is gradually fading and is only half as dark as it was. I do not expect any more lesions in this monkey before spring.

The pellagra organism belongs to the higher bacteria in an unclassified group. It may be a streptothrix, as in many ways it fulfils Tuttle's excellent description of a streptothrix as given in Park's Bateriology, but it probably belongs to an unknown fungus family, in which there is a double cycle as occurs in the moss family. I have been able to study this organism through both of its cycles. The human cycle takes place in about the following manner, as worked out through my cultures: The spores of this organism are deposited in the deepest layer of the skin by some blood sucking insect, where they begin to grow by sending out long fine mycelia that enter the lymph spaces along the basement membrane. These mycelia contain within them many very tiny spores which are liberated in the blood stream by the dissolution of the mycelia. Whether this takes place before these mycelia are broken off or after, I do not know, but they are very resisting to destruction. These are able to pass out of the capillaries through the stomata due to their extreme small size, as I estimate them to be about one-tenth micron in diameter. Here they begin to grow and develop into the second stage by sending out mycelia that develop into bacillus-like bodies that are actively motile.

This organism is a facultative aerobe, and when grown on suitable media forms a false membrane on top of the culture. When stained by Wright stain in fresh cultures, it is about the size of a small tubercle bacillus, but stain very poorly. After a few generations on artificial media it grows larger and, stained with above stain, cannot be distinguished from a culture of the diphtheria bacillus, as stained by Loeffler's method. When grown in bouillon from old culture, I have found filaments so fine that they were hardly visible with the 1000 magnification, while others were nearly a micron in diameter, and in some of my old culture that have been transplant-perhaps a dozen times on blood serum they very much resemble a potato bacillus. This occurs only after several generations on artificial media.

The primary blood culture will stain only with Wright's blood stain; after several generations they acquire more staining properties and are then stained with hot carbol fuchsin.

It grows best on moist Loeffler serum or bouillon, or acetic agar. It will not grow on plain agar or glycerine agar. Within the body I do not think that it ever forms spores unless it comes in contact with the air. I base this opinion upon the character of the pathological lesions.

From my study of this disease I think Sambon's theory is correct, that it is transmitted through the bite of some insect, as the stock fly, mosquito, flea, bedbug, or some other blood sucking insect. We have never had a case that did not occur in unscreened houses. As to the maize theory, I think from a little observation of my own that corn unquestionably harbors the host at some period of its cycle, as I found a similar organism in some bole worms in green corn that grew close to several cases of pellagra. With the exception of a few protozoa and spirilla there is absolutely nothing known of our parasitic microorganisms outside of the body, and then only in the insect that carries them. Why could not corn harbor the host? I am going to describe a theory of my own as to the mode of transmission of this disease. I shall illustrate this theory with the mosquito and malarial plasmodium. In some of our dense swamps of the tropics, man is scarcely known, due to the virulent malaria. Yet there are unnumbered billions of infected malarial mosquitoes there. Billions of these mosquitoes never saw a man, as their life cycle is less than six weeks, yet they are infected. It is through the increased virulence of the malarial plasmodium that grows under certain favorable conditions in the

swampy waters; it is able to infect the mosquito as it is able to do so when it is sucked from an infected man's blood, as the step up from the water to the mosquito would be no greater than from the mosquito to man, or vice versa. Man can live in one of these infected swamps, as has been proven, and drink this infected water, if he can keep the mosquito away without becoming infected. This same theory applies to corn; when grown in a moist, hot climate it permits this organism to grow with such virulence that it is able to infect some insects, and by them is conveyed to man. This organism, I think, was sown broadcast throughout the United States when the Agricultural Department at Washington imported this infected corn and distributed it to the farmers as foreign corn for them to try. All of our cases have practically occurred on the Wichita River or some tributary, and all European writers say that water seems essential to its growth. The reason I assign for this is that it is hotter along the river and creek valleys, the dews are much heavier than in the highlands, and the most essential things to the growth of this organism are moisture and heat, and these we get, especially in a rainy season along the creek and river valleys.

Below I am giving a list of forty-eight cases of pellagra that have occurred in the vicinity of Wichita Falls. Some of these cases were imported and died here, but the great majority were natives. Twenty-six of this number occurred in nine families or can be traced to them. I have not had the time to work out in detail whether any more of these cases came from infected houses or not.

My first case of pellagra occurred in 1909. This case was one that had severe hemorrhage from the uterus. She passed into other hands for further treatment. She had the rash, nervous symptoms, sore mouth, and a slight diarrhea, being typical in every respect. In April, 1913, I was called to treat her sister-in-law, who was suffering from pellagra. I had delivered this woman seven months previously of a child, and at the time of my first visit I ordered the weaning of the child. This patient gradually grew worse, her baby took what I diagnosed as pellagra in July. The little fellow lasted only three weeks. I made my diagnosis from the following symptoms: Sore mouth and serious diarrhea, stools being passed every few minutes; dry skin, with harsh branny desquamation, temperature that ran over 150° during the last days of illness, increase of muscular movements that became constant toward the last, and finally death in convulsions. I made a blood smear from this child and was able to demonstrate the organism. The mother of the child gradually grew worse and died on December 22. The mother of the first case now is suffering from pellagra, I have been informed by her physician.

Second Series: I was called in to treat a little fellow for eczema, and found the mother and three children with the disease. I made some photographs of this child. They soon left town and I lost all trace of them.

Third Series: I have a patient whose father died with this disease in Big Springs, Texas; now two of his sisters are afflicted.

Fourth Series: I had a patient die with pellagra in 1913. Her aunt had died the year before, and her mother had it at that time.

Fifth Series: I was called as a witness in a case of insanity due to pellagra, in April, 1913. Her doctor told me that she had not seen her parents for a number of years, but hearing that she was sick they made her a visit and were in the house only four days. Her father took the disease and died in less than a year.

Sixth Series: I had another patient who had pellagra, and there was another family living with her to do the housework. The ten-months-old child of this other woman took pellagra and died in three weeks. This was a breast-fed baby with every symptom that the other child had. These people were exceptionally filthy; they first lived in one house for about two months, then moved next door, and perhaps lived that long in the latter. I have treated a case of pellagra in each of the families that moved in after they left, this woman having infected three families.

Seventh Series: Dr. Amason reports to me that in one of his families the mother and son both died of this disease.

Eighth Series: Dr. Joe Daniels reported he has a man and wife suffering from this disease. I saw these cases with Dr. Daniels and confirmed his diagnosis.

Ninth Series: Dr. W. W. Shirley reported a mother and baby with pellagra in 1913. The child died, but he thought he had cured the mother at that time.

The other twenty-two cases occurred singly. I treated five of this number and one or more members of the families of five of the other cases, and know that these cases are authentic.

I have tried to locate every case of pellagra that has occurred in the vicinity of Wichita Falls by having each doctor furnish me with a list of the cases that he has treated.

In conclusion, I would like to call attention to the way in which these organisms grow within the body. In this disease, as in many others, we have areas where only they will grow. In this disease they grow best in the lymph spaces along the basement membrane of organs that either contain epithelium or are covered by it, in the skin, intestinal tract, including mouth, genital tract, uterus, respiratory, including the nose and pharynx, brain and spinal cord. These organisms live off of the excretions of epithelial cells, and are distinct saprophytes. Their toxic action is due to the liberation of a ferment within the blood, for the destruction of these organisms that gives the peculiar cachexia of this disease. When these organisms gain access to some organ as the uterus, bladder, or intestinal tract, where there is an excessive growth due to the abundant blood supply, we find chilly sensations, with a rise of temperature. These chills may occur every few hours. I have seen the temperature as high as 106° F. But we may see pellagrins die without ever having a rise of temperature.

My work upon this organism has been done with the most rigid technique; some of these cultures were made in the home of patients, some in the hospital, and only one in the office, and the same organism obtained each time in pure culture. I have utilized every case where there was any hope of obtaining satisfactory culture, as I do not think one could hope to obtain a culture unless the patient had an elevation of temperature with preceding chill. The higher the temperature the more likely we are to obtain a culture, and the more virulent it will be.

I have fulfilled Koch's laws in the chicken, and it looks now as if I am going to do the same in the

monkey, as the first change in a yellow negro, who is suffering from pellagra, is for his skin to turn black, as it has done in the monkey.

My antigen test I consider the most important, as it enables the physician to make his diagnosis before it is too late to benefit the patient; as many cases of pellagra never have any skin lesions, or only very late in the disease. This test has been employed in only three cases, as they are all of the patients that I have been able to get to let me make this test.

From the description one can see why I was able to confirm the statement of Dr. C. Harris of New Orleans on this organism, that it is a filterable virus. I also think Tizzoni has been working with this organism, but he has studied only one cycle and has used too dry a medium to get typical growth. The organism described by him corresponds to one cycle of my organism which, in a dry culture, looks like a streptobacillus. I have obtained this organism three times from the blood stream, twice from cultures from blister fluid, twice from the spinal fluid after death of the patient, and three times from blood smears from the blood, and six times from blister fluid smears.

Any one ought to be able to obtain this organism from the blood by culture methods, if he will use a sterile syringe and pick up the median cephalic vein under strict aseptic technique. One c.c of blood should be drawn and planted on blood serum that has been coagulated in a hermetically sealed tube. Such a blood slant should contain about one c.c. of fluid above the coagulated serum, as this is very essential to the growth of these organisms; the use of cotton plugs permits the evaporation of this fluid and leaves the medium too dry. This blood should never be collected unless the patient has a high temperature, and the sooner after a chill it is taken the better is the chance of getting a growth.

I know my work is based on very few cases, but I believe I am on the right road, as I have more tangible results than any other investigator of this disease. In my present location I am unable to get but few cases each year, and one cannot do with private patients as he would like to, as they will not submit to blood examination. It is to get other investigators interested in this problem that I prepared this brief review of my work upon this disease that is so serious in our Southland.

A FREQUENTLY UNRECOGNIZED SYMPTOM-COMPLEX.

By WILLIAM H BEST, M.D.,

BROOKLYN, N. Y.

ASSISTANT VISITING PHYSICIAN, DEPARTMENT OF CUTANEOUS DISEASES AND SYPHILIS, KINGS COUNTY HOSPITAL; ATTENDING PHYSICIAN, BRADFORD STREET HOSPITAL SKIN CLINIC; DERMATOLOGIST, BROOKLYN INDUSTRIAL SCHOOL.

In the past three years I have observed on several occasions a symptom-complex which, although seemingly closely related to the febrile exanthemata, possesses a certain sequence of symptoms that, it seems to me, differentiate it from the others of this group, namely, rubella, rubeola, scarlatina, and Dukes' disease. When Dukes in 1900 first described the "fourth disease," he was met with much opposition, and although there are still some who deny it to be a distinct disease-entity, I think that Weaver[1] in England and Winfield[2] and Simpson[3] in this country have shown that it deserves a place in our medical nosology. It is therefore with no little trepidation that I offer still another distinct condition, and ask for it a separate place in what seems to be an already overcrowded nomenclature.

Either this symptom-complex is a very rare condition, or it is not being recognized as a distinct entity. The latter is more probably the case. On studying the literature I find that Dr. John Zahorsky[4] of St. Louis has reported, with case histories, under the title of "roseola infantum," a symptom-complex which corresponds with the one that I have observed. With this one exception, I have been unable to find any reference to it. Zahorsky has pointed out that some of the earlier writers (Meigs and Pepper[5]) recognized this syndrome and classed it with toxic erythemata. An analysis and study of thirty-seven cases shows the following salient features of this symptom-complex.

Season: Three cases occurred in January, 6 in February, 4 in March, 4 in April, 3 in May, 2 in June, 2 in August, 2 in October, 6 in November, 5 in December. While the cases were distributed throughout the year, there seems to be a preference for the winter and early spring, since 28 of the cases occurred in the six-months' period from November to April.

Sex: There is little preference here; 17 cases occurred in males, and 20 in females.

Age: in 20 cases the patients were under one year, between 1 and 2 years old in 13 cases, between 2 and 3 years in 3 cases, and over 3 years old in only 2 cases. The evidence here shows it to be distinctly a disease of infancy, 33 of the patients being under 3 years of age. The predisposition, apparently, is in inverse relation to the age.

Onset: In all cases the onset was sudden. The child while apparently in good health suddenly becomes fretful and disinclined to play, the eyes become dull, or during the night the child is wakeful and restless. The mother or attendant upon investigation finds the child feverish, with a hot, dry skin.

Temperature: The temperature, while not recorded in all the cases reported, varied from 102° to 105° F. The individual cases showed very little daily fluctuation, the morning temperature being about 103° and the evening about 104°. This temperature was steadily maintained until the appearance of the eruption, when it dropped by crisis to normal or almost normal. In one of my cases, for instance, the temperature was 104° at 10 P. M. and the child was restless and fretful until midnight, at which time she fell asleep. The mother, worn out by the several days of vigilance, lay down and shortly after fell asleep also. When she awakened it was broad daylight, and she ran to the baby's crib, only to find the child still peacefully slumbering but with a rash all over its face and neck. I was called immediately, and when I arrived the child was sitting up in its crib, apparently well and content with things in general. Its temperature was 99.8° by rectum.

Eruption: In 12 cases the eruption appeared on the third day, in 24 cases on the fourth day, and in only two cases on the fifth day after the acute onset of fever. The eruption appears first on the face and neck and spreads in a quick wave-like manner down over the body. This process occupies as a rule not more than a few hours, and not infrequently the rash starts to fade on the face and neck at the end of 24 hours. In two of my cases there remained no vestige of the eruption after 72 hours.

The lesions are at first bright red, discrete, pinhead to split-pea sized macules, which soon become flat, slightly-raised papules. As the lesions grow more numerous, they become confluent, making various size patches. When the eruption is very profuse, patches the size of the palm of one's hand are not uncommon on the buttocks and inner side of the thighs. While the eruption usually starts on the face and neck, it is more profuse on the trunk and extremities; hence it tends to maintain its discrete character on the face and neck, while on the trunk and extremities erythematous patches interspersed with discrete lesions may be the presenting picture. In none of the cases reported was desquamation noted, and I saw it in only one of my own cases. There was a fine branny scaling more or less over the body, with coincident itching. The scales were coarser in those areas where the eruption was more profuse. In another case the eruption was followed by an eczematous condition of the forearms, which cleared up promptly under appropriate treatment. I must interpret this eczematous sequela as the result of itching and irritation, produced by attempted rubbing and scratching.

Lymph glands: In only 6 cases were the cervical glands palpable.

Gastrointestinal disturbance: Seven of the cases had suffered from gastrointestinal disturbances. The remaining 30 cases were all robust breast-fed or bottle-fed infants. During the fever stage 9 showed signs of gastrointestinal disturbance; that is, 3 were constipated, 5 showed some diarrhea, and one a marked tympanitis. In only 2 of the cases with increased movements were the stools distinctly abnormal in character.

Respiratory tract: In 4 cases there was slight cough and coryza. These symptoms were probably coincident with, rather than part of, the affection. In most of the cases the fauces and pharynx showed varying degrees of congestion. This congestion spread to the tongue and mucous membrane of the mouth, subsiding with the fading of the rash. In one case reported a few follicular spots were noted on the tonsils. Aside from this, no spots or patches were observed in the mouth or throat.

Blood examination: The only abnormal feature of the blood was a mild leucocytosis varying from 11,500 to 16,000 whites, with 75 per cent. to 80 per cent. of polymorphonuclear cells. The increase in the polymorphonuclear cells was at the expense of the lymphocytes. I regret that I did not make a second blood count in my cases, after the appearance of the eruption.

Urine: The quantity was always markedly diminished, dark in color, with increased specific gravity. Albumin was present in traces, in all the urines examined. Tests for the presence of blood, indican, and sugar proved negative. The microscope showed some epithelial cells, and in some cases actively motile bacilli. No casts were found. These urinary findings are of only a negative value, as they are what might be expected in any febrile condition.

Previous eruptive conditions: Two cases had a previous history of rubella, 2 of rubeola, one of scarlatina, and in one case a previously unidentified eruption. I was myself fortunate enough to have seen, in two of my cases, a previous eruptive fever, which I had diagnosed as measles and German measles respectively. Both cases were so typical that I am confident I did not err in diagnosis.

Contagion: In none of the 37 cases was there any contagion noted either to or from the patient, although in many cases there was ample opportunity for it. The eruption not appearing till the third or fourth day, there was not as a rule much incentive for isolation during the time preceding the eruption.

Complications: In no cases were any ear, lung, heart, or kidney complications noted during or following the attack.

Summary of symptoms: To sum up, then, we have here a symptom-complex, consisting of a sudden high temperature with but little daily variation, developing in an infant under 3 years of age, and lasting 3 or 4 days, during which time the child appears very toxic and is drowsy and fretful by turns. With the exception of congested fauces and pharynx, physical examination, and examination of the blood, urine, and stools reveal no cause. There is no general glandular enlargement, although rarely the cervical glands are palpable. On the third or fourth day a morbilliform eruption appears on the face and neck, spreading in a quick wave-like manner over the body and disappearing in 48 hours. Coincident with the appearance of the rash the temperature falls by crisis, the child appears well and happy, and there remain no complications or sequelæ about which we need concern ourselves.

Differential diagnosis.—Erythema scarlatinoides: I am of the opinion that erythema scarlatinoides, while described as a special disease entity, has been made the scrap-basket for a number of clinically similar erythematous eruptions, and I fear that some cases, which really belong to the symptom-complex I have described, have in the past been dumped into this basket. Probably, though, rubella has been made to assume the responsibility of some of these cases. In describing erythema scarlatinoides, Stellwagon ("Diseases of the Skin") says that although the eruption is usually scarlatiniform it occasionaly presents a morbilliform appearance; that while in certain severe cases the systemic disturbances persist for several days after the appearance of the eruption, yet not infrequently they disappear with its outbreak, and that while desquamation is usually present, varying from fine branny scales to large thin pieces, occasionally desquamation is not perceptible. Given, then, a case of erythema scarlatinoides with a morbilliform eruption, the systemic disturbances subsiding with the appearance of the eruption, and a scarcely perceptible desquamation, we have a syndrome resembling in its essential features the symptom-complex above described. If these cases are eliminated from the erythema scarlatinoides group, there should be no difficulty in differentiating the remainder from our symptom-complex.

Rubella: With rubella is probably the greatest danger of confusion. In fact, I should hesitate to make a differential diagnosis on the eruption alone. In German measles the eruption may be a lighter red; the child rarely appears so extremely sick; does not have such a high temperature; the febrile period is much shorter (usually from 12 to 24 hours), and the temperature remains constant with the appearance of the eruption, coming down by lysis as the eruption fades. General glandular enlargement with occasional tenderness of the postcervical and submaxillary glands is another characteristic of rubella. Hess (*Archives of Internal Medicine*, June, 1914) reports a constant lympho-

cytosis in the blood examination of patients suffering from rubella.

Rubeola: The onset of measles is with a varying degree of catarrh of the eyes, nose, throat, pharynx, and larynx. By the end of the second day Koplik's spots may be seen on the buccal mucous membrane. These symptoms have not been regularly observed in our symptom-complex. In measles it is not uncommon to have the highest temperature during the first two days of the eruptive stage, falling by lysis as the eruption fades. The eruption in our symptom-complex lacks the characteristic crescentic arrangement seen in measles.

Scarlatina: Scarlet fever has a short period of invasion (12 to 24 hours), at the end of which time the eruption usually appears, and during which time there is usually some vomiting. The rash is bright red and punctiform, and appears first on the chest and upper extremities, whence is spreads downward over the body. While the face usually shows a flush, it is rare to see a true scarlatinal rash in this location. The rash increases in intensity until the third day, when it begins to fade. This is followed by marked desquamation. The temperature runs *pari passu* with the eruption.

Dukes' disease: The eruption is red and punctiform, and in this respect resembles scarlatina. The prodromal period is mild. To quote from Dukes himself, "The rash is usually the first indication of the disease, and may cover all of the body in a few hours. There are few general symptoms. In mild cases the temperature is slightly elevated, but the pulse rate may be unaffected." Here again the symptoms, especially the mild temperature, persist until the rash disappears.

The eruption of erythema multiforme, a fading purpura, a drug rash, and in tropical countries dengue, might resemble the eruption of the symptom-complex, but the sequence of symptoms is lacking.

While in all the foregoing diseases there are certain symptoms in common with our symptom-complex, there is one symptom present in the latter which is lacking in all the former, and I believe it is pathognomonic of the condition. *That symptom is the drop in temperature by crisis, and the feeling of well-being that the patient experiences, upon the appearance, or shortly after the appearance, of the eruption.*

Etiology.—Taking as a basis the phenomena of infection as interpreted by Vaughan, this disease can be placed, I think, in the class of "protein-fevers," the result of parenteral protein digestion. It remains to be determined, however, first, whether the foreign protein is an organized or living protein, or an unorganized or non-living protein, and, second, what is the portal through which this foreign protein enters the system. Gamaleia in 1888 showed that fever followed the introduction into an animal of dead as well as live bacteria, also non-pathogenic as well as pathogenic bacteria. He also observed that the less virulent the infecting organism, the higher and more prolonged the fever. Judging from his experiments, then, it is possible to produce fever by the introduction of non-living, unorganized proteins into the body. Vaughan by experiment and logical deduction has shown that since the body cells have the power to utilize for their structural work only the simple proteins, such as the amino-acids, when a protein of a more complex nature is introduced into the organism it must be broken down into amino-acids before the body-cells can utilize it. This is accomplished in the alimentary tract by the various juices containing the ferments, and the amino-acids are absorbed through the intestinal wall and carried by the blood and lymph to the cellular tissues of the body, each cell selecting such of the simple proteins as it needs for its maintenance. If, however, through some fault of the digestive juices and ferments, the proteins are not reduced to amino-acids, so that the partially broken down or more complex proteins are absorbed, or if complex proteins are introduced into the body by some other route, as, for example, the pollen protein through the respiratory tract in hay fever, or if bacteria which are living, organized proteins enter the body, the body cells respond to this invasion by elaborating a specific ferment for the particular complex protein, which ferment reduces it to the amino-acid stage. This is the process of parenteral digestion. According to Vaughan every complex protein molecule contains a poisonous group and a non-poisonous group, and it is the splitting up of the complex protein molecule and the liberating of this poison group which causes the symptoms in "protein fever," and jeopardizes life. When this poison is liberated in enteral digestion it is prevented from entering the circulation by the protective power of the intestinal wall.

There are three factors in our symptom-complex that I interpret as being the result of the introduction into the body of a non-living, unorganized protein. First, the absence of any evidence of contagion; second, the lack of lymph-gland involvement, which is a rather constant accompaniment of all the generalized bacterial infections; and, third, which I consider the most important, the drop in temperature on the appearance or shortly after the appearance of the eruption. This unorganized foreign protein, after gaining entrance, is carried to the tissues of the body. The large skin area probably gets the major portion. The process of sensitization begins, during which period the patient has a fever, due to certain chemical alterations to the structure of the cellular tissue for the production of the specific ferment. At the end of 72 or 96 hours sensitization is complete, a specific ferment is produced, the complex protein is split, and the poison group liberated. The irritation of this poison group in the skin causes congestion and round cell infiltration of the derma, and where present in large quantities may even cause a small hemorrhage into the derma and subcutaneous tissue. On account of this protein poison being so close to the surface of the body, it is easily and quickly eliminated, the temperature drops, the child appears well, and there remains only the repair of the derma from the irritation of the protein poison.

If a living, organized protein were the provoking cause, then there would be a double process, namely, a growth of the virus with sensitization in one part, while in another part ferment production and parenteral digestion. We should expect here the continuation of the fever after the appearance of the eruption, and its continuation until sensitization had reached the point where all the invading microorganisms were destroyed. This is probably the case in scarlet fever, measles, and German measles.

Lastly, as to the port of entry of this unorganized protein. With few exceptions the patients ranged between five months and two years of age.

It is during this period that the digestive juices are being called on to attack new kinds of proteins introduced into the gastrointestinal tract. Surely they ought not to be censured if they fail in an occasional attempt.

I think it is fair to assume that either on account of the introduction of some new protein into the gastrointestinal tract and the inability of the digestive juices to reduce it to amino-acids, or if on account of a mild catarrhal condition of the stomach and upper intestine the digestive juices have been so altered that they are unable to reduce the amino-acids such proteins as they had been capable of digesting under normal conditions (that is, normal enteral digestion), then as a result the semi-broken down, complex proteins are absorbed and the process of parenteral digestion is established. I do not think it essential that gastrointestinal disturbances (*i.e.* vomiting, diarrhea with abnormal stools, etc.) need be a constant accompaniment in order that one may establish an intestinal origin for this symptom-complex. I should argue, on the contrary, that vomiting and diarrhea would so increase the elimination that very little of the semi-broken down complex protein would be absorbed.

Conclusions.—From an etiological as well as from a clinical viewpoint I do not think that this symptom-complex bears any relation to rubeola, rubella, scarlatina, and Dukes' disease. From a clinical viewpoint it probably has been, and from an etiological viewpoint it probably could be, relegated to that rather irregular and diversified class of conditions summed up as erythema scarlatinoides. However, on account of the almost constant and typical course of this disease, I think it deserves a separate place in our medical nomenclature.

TRICHOCEPHALUS DISPAR INFECTION.

WITH REPORT OF A CASE.

By RALPH R. MELLON, M.SC., M.D.,

ANN ARBOR, MICH.

ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS, AND DIRECTOR OF THE LABORATORY OF CLINICAL PATHOLOGY, UNIVERSITY HOMEOPATHIC HOSPITAL.

This infection is thought to be a harmless affair in the vast majority of instances, if we are to judge by opinions expressed in the various textbooks on Clinical Diagnosis and Internal Medicine. Emerson[1] says that it is one of the most common of intestinal parasites, and that autopsies indicate its presence in 100 per cent. of the cases in Southern Italy. It is present in the stools of 45 per cent. of the population in some parts of Germany and occurs in 10.3 per cent. of adults in this country. He recognizes, however, that in some cases it may give rise to severe symptoms and even death. He cites an article by Becker[2] which I have reviewed. This author also mentions the fact that the parasite is generally considered as living a commensal existence in the human intestine, but does not consider this contention exactly justified, as is shown by his review of the literature and his own cases.

Simon[3] describes the organism in his Clinical Diagnosis, but makes no reference to its pathogenicity. Wood[4] relates that mental symptoms have been occasioned by it, but as a rule it did not cause symptoms. He quotes Gerard, who refers to the possibility that the lesions induced in the mucosa of the appendix favors a secondary infection of that organ.

The worms are 40 to 50 mm. long and usually occur in pairs. The anterior part is threadlike, while the posterior part is much thicker, in which respect they resemble an ordinary whip. The posterior part is usually coiled like a watchspring in the male, while it is either straight or comma-shaped in the female. The eggs are very striking and are not easily mistaken for anything else. They measure about 20 to 25 mm. in width and about 50 mm. in length. They are colored a dark brown, have a doubly contoured membrane and two highly refractile plugs at either pole. A granular yolk fills the center.

Askanazy[5] says that they are passed with the feces and developed to larvæ in moist places and may live in their shell for as long as five years. They are usually swallowed with the water, or with dirt by children, which gives opportunity for the development of the mature parasites. About four weeks later the eggs are found in the stools.

Pascal[6] reports a case of a little girl who developed anemia and died with symptoms of cerebral irritation. The trichocephalus was present in the cecum and colon in large numbers, although the brain was negative. Barth[7] reports a similar case with the exception of the meningeal symptoms. The autopsy showed a completely normal central nervous system. The colon contained a large number of the organisms. Gibson reports a case in a six-year-old girl who gradually developed a condition of nervous irritability. Inability to dress herself through lack of coordination was soon followed by interference with her speech from the same cause. Finally, paralysis of the extremities and loss of speech supervened. Moderately large doses of calomel produced a rapid improvement and ultimately a complete cure.

Burchardt[8] gives an instance of a nineteen-year-old man who vomited several times a day from an unknown cause. Later, he had profuse diarrhea. After temporary improvement following the Karlsbad cure the symptoms returned and blood appeared in the vomitus. Severe vomiting and purging three and four times a day. Gradually he grew very weak and developed severe pains in the region of the transverse colon. A microscopical examination of the feces showed the eggs of the *Trichocephalus dispar* in every preparation. From the number of eggs he calculated that there were about 500 males and 500 females in the intestine. The patient then developed signs of peritonitis in the right hypochondriac region. Santonin was administered after which he repeated the Karlsbad cure. Marked improvement followed. Several months later the symptoms returned, this time accompanied with severe icterus and complete aphonia. Later he completely recovered, although Burchardt did not find out whether the parasites were driven from the intestine owing to his inability to procure specimens for examination. Two other cases are reported in the group with like symptoms.

Another patient of Burchardt's gave a history which revealed the fact that he had visited a school where the above patients attended. He believes

that they all contracted the infection from the drinking water, because the well lay very near a latrine.

Morsasca[9] gives a case of severe progressive anemia with frequent diarrhea and abdominal pain. The stools are bloody and many eggs are present. Anthelmintics cured him.

Moosbrugger[10] reports a case of a boy one and one-half years old who had suffered for 24 days with a slimy, bloody diarrhea. In addition, he had a high grade anemia in spite of a good appetite and nourishing food. Large numbers of the trichocephalus eggs were found in the feces. After a severe attack of bronchitis his mother was able to get twenty-six of the worms from the mucosa of the rectum while the child was straining. Treatment was unavailing. A second case occurred in a two-year-old boy who had frequent evacuations, watery in character and containing much blood. No vomiting or nervous symptoms. Many eggs were found in the feces. Treatment was not successful. At the autopsy it was found that the large intestine contained a thick mucous exudate and many trichochepalus worms knotted together in clumps, some of which contained thirty. In some places the colon was much injected and at other places pale. In one location a bleeding ulcer was found.

Megnin[11] reports cases of pernicious anemia in dogs, in whose cecums he finds several hundred worms. He suggests a connection between the parasites and the anemia, but does not attempt to establish it.

Becker (*loc. cit.*) observes the case of a 22-year-old cook. The blood count was reds, 3,456,000; whites, 6,250, and the hemoglobin 35 per cent. Marked poikilocytosis and many macrocytes. No nucleated forms were seen. A differential white count showed: Polymorphs 69 per cent., lymphocytes 26 per cent., eosinophiles 2 per cent., mononuclears 3 per cent. The eggs were found in every preparation of the feces. There were no physical signs with the exception of a loud mitral murmur. She derived no benefit from a month's treatment with liquor ferri sesquichlorati. She was then treated with daily injections of benzene, five drops to a liter. The patient gradually improved, and was finally cured. Fourteen days following the cure the red count was 4,350,000 and the hemoglobin 50 per cent. A week later it was 5,100,000 with a hemoglobin of 70 per cent. The patient was dismissed at her own request, and although numerous observations were made, no eggs could be found in the stool.

As the blood findings in the above case resembled those of chlorosis, Becker successfully eliminated this condition as a diagnostic possibility by the administration of antichlorotic treatment over the course of a month. Although the blood findings are similar, the great decrease in the number of red cells combined with extensive morphological changes serves to distinguish. Then the fact that nucleated forms are often found in this condition forms a differential sign of value. No megaloblasts have been reported, however.

Becker divides the symptoms of this infection into three groups, as follows:

1. Intestinal: Severe catarrh of the colon with copious diarrhea. Ulceration, blood in the stool, and perityphlitic symptoms. Peritoneal phenomena and vomiting.

2. Nervous system: Brain symptoms, headache, vertigo, aphonia. Meningeal symptoms, reflex phenomena of various kinds are often present, such as disturbed digestion and deterioration of the blood.

3. Blood symptoms: Anemia with headache, vertigo, palpitation of the heart, and debility associated with abdominal pains.

This organism occurs in varying numbers in the intestine. Rudolph found over 1,000 in his case, Bellingham found 100, Heller 60 to 100, Askanazy 50 to 100. Moosbrugger[10] in two cases found 887. It is possible that they produce an anemia in the same manner as the *Bothriocephalus latus* or fish tape worm and the *Ancylostoma duodenale* or hookworm.

Askanazy[12] has found that the gut of this parasite contains small brown and black pigment granules which give it a diffuse brown color. That this pigment is iron containing can easily be demonstrated by the potassium ferrocyanide-hydrocloric acid reaction. The pigment is found exclusively in the gut of the parasite, and can only be derived from the hemoglobin of the host through the mucosa of the intestine.

It can be seen in the sections that the parasites burrow into the mucosa in such a way that the thin fore part of the body forms a loop, with the anterior end just protruding through the wall of the host's intestine. Whether the trichocephalus swallows whole blood corpuscles or takes up hemoglobin alone is not known, but he has observed within the esophagus of the parasite a cell resembling a polymorphonuclear which caused its distention to 10 microns. Sometimes, however, its caliber is normally that size.

During life all of the parasites are attached to the mucosa and are not driven off by vermifuges, so that it is an extremely rare thing to find them in the stool. Shortly after death they begin to drop off and in 48 hours most of them are found free in the intestine.

It is supposed that certain diseases may alter the intestinal wall or its blood supply so as to make the environment distinctly unfavorable as a habitat for this organism. As evidence for this contention, Becker cites the case of Moosbrugger.[10] A complicating attack of severe bronchitis in a one and one-half-year-old boy was supposed to be the cause for the appearance of the worms in the feces. The child's mother was able to take 26 from the rectal mucosa.

The rôle of this organism in appendicitis has been much discussed. Aschoff (*loc. cit.*) says that since the parasites are able to bore into the living tissue they may favor the development of pathogenic bacteria. But usually there are no symptoms of typhlitis when these organisms are present, while appendicitis usually occurs without their presence. However, there has been very little careful search for either the parasites or eggs in these cases.

Case Report.—Patient is a little girl three years old Although American born, she has lived in the Philippines for the past year where her father is employed by the Government. Her constitution is not strong, although she has had no sick spell previously. About five or six months ago, her appetite disappeared, and marked abdominal bloating was noticeable. She did not sleep well, not infrequently awakening with a shriek. At these times, clonic spasms of the muscles occasionally occurred. Not infrequently, a generalized tonic spasm produced rigidity of the entire body.

About two and one-half months ago, she suddenly developed a moderate jaundice with a temperature of 104°. In twenty-four hours, the temperature was normal and the jaundice gradually disappeared. The Tri-

chocephalus eggs were found in practically every preparation examined. One c.c. of feces contained approximately 200 eggs. A blood examination showed: reds, 3,330,000; whites, 8,200; hemoglobin, 70 per cent. Differential: Polymorphs, 36 per cent.; large mononuclears, 42.2 per cent.; small lymphocytes, 14.5 per cent.; eosinophiles, 7.3 per cent. Cina was administered in the first dilution ten drops per day for a week. The next week, two saline purges were given. The following week, santonin, the same strength and frequency of dosage as the cina, was administered. The bloating in the abdomen nearly disappeared and the whole symptom complex was greatly improved.

During these three weeks, six examinations of the stools were made and at no time had the eggs completely disappeared. The stools were almost normal in color and consistency. At the end of three weeks more, with no additional treatment, all symptoms had disappeared, the stools were normal and no eggs could be found after three examinations. The blood count at this time was: reds, 4,185,000; whites, 10,400; hemoglobin, 85 per cent. (Fleishl.) Differential: polymorphs, 65.5 per cent.; mononuclears, 1.5 per cent.; transitional, 1 per cent.; eosinophiles, 4.5 per cent.; large lymphocytes, 8 per cent., and small lymphocytes, 20 per cent. At the time the patient had a mild streptococcic coryza, which probably caused the slight polymorphonuclear cytosis.

Summary.—Although it is not the usual thing for this parasite to assume a pathogenic rôle, it is not as harmless as the ordinary text-book on Clinical Diagnosis would have us suppose. Since it is a blood-sucking organism, the appearance of its eggs in the feces should not be considered too lightly in cases of obscure anemia. It is quite noteworthy that the rapid disappearance of the clinical symptoms and blood picture occurred simultaneously with the absence of the eggs in the feces. This forms the best evidence that I possess of the pathogenicity of the trichocephalus in this case.

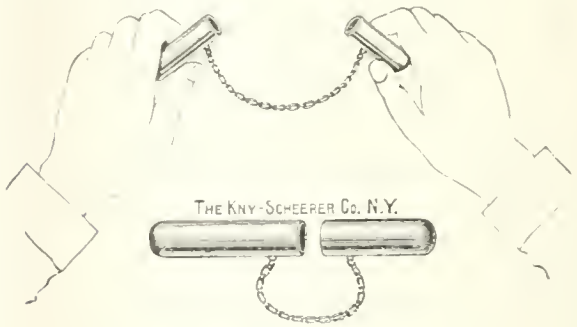
BREAKING GLASS TUBES CONTAINING SUTURE MATERIAL.

By EUGENE H. POOL, M.D.,

NEW YORK.

ALTHOUGH catgut and other suture materials put up in sealed glass tubes are used extensively, an efficient means of breaking these tubes has been lacking. The usual practice is to cover a tube with gauze and break it with gloved hands. By this method not infrequently gloves and hands are cut by broken glass and in the course of a year considerable gauze is wasted. To obviate these disadvantages we have adopted at the New York Hospital a simple and cheap device. Two metal cups, connected with a chain, as shown in the illustration, are used for breaking the glass.

The success of the device depends upon the fact that the glass tubes of most, if not all, supply houses have a standard distance between one end and the filed line or fracture line near the center; the distance between the filed line and the other end is somewhat variable. *The shorter cup is made the same length as the fixed distance* between the file mark and the end.



Cups for breaking glass suture containers.

Application. Holding the short cup in the left hand, that end of the glass tube which is of uniform length (this is usually the shorter end) is introduced into it. *The filed line is placed away from the person holding the tube.* The other cup is then placed over the other end of the tube and with a sudden sharp bending motion the tube is readily broken.

107 EAST SIXTIETH STREET

Medicolegal Notes.

Physician's Liability for Chauffeur's Negligence.—A physician, having been driven to his club in his automobile, ordered his chauffeur to return in the evening. His wife, late in the afternoon, having authority to give orders to the chauffeur in the use of the car in her husband's absence to do "anything reasonable," directed the chauffeur to take her to the club. While on the way they discovered an injured woman by the roadside. The physician's wife stopped, and, finding the woman too badly injured to be moved, directed the chauffeur to go for a doctor. This he did, finding a doctor who got into the car. On the way back to the scene of the first accident the car collided with a wagon and the doctor was injured. In an action for his injuries against the physician for his chauffeur's negligence it was held that the physician's wife under the circumstances was not exercising exclusive control over the chauffeur, and, she having authority to direct the chauffeur to go for a doctor, her orders to him to do so did not destroy the relation of master and servant otherwise existing between the defendant and the chauffeur, and the defendant was therefore liable for the consequences of the chauffeur's negligence.—McHarg v. Adt, 163 N. Y. App. Div. 782, 149 N. Y. Supp. 244.

Suggestion of Insurance to Jury in Malpractice Case Causes Reversal.—In an action against the visiting senior surgeon of a hospital for damages for his alleged negligent failure to care for the plaintiff's dislocated knee, the evidence was held to make a close case as to whether the surgeon had neglected to care for the plaintiff to his injury or whether the want of treatment was not in accordance with the plaintiff's expressed wishes. The surgeon was serving without pay. The plaintiff's counsel sought to appeal to the prejudice of the jury by placing the defendant, contrary to the facts, in the position of one owing a special duty to the plaintiff out of the many patients in the hospital. On appeal from a judgment for the plaintiff, it was held that the action of the plaintiff's counsel in asking the jury whether they were interested in any insurance company issuing policies for protection against liability for injuries from malpractice, was ground for reversal.—Rothenberg v. Collins, 161 N. Y. App. Div. 387, 146 N. Y. Supp. 762.

DIGITALIS DOSAGE.

IN the development of the various branches of medicine the department of therapeutics has proceeded more slowly than most of the others, especially in the matter of drug treatment. The activity of the laboratory has added a few valuable remedies to our armamentarium, but much of the research on this subject has tended rather to disprove the value of many drugs, both old and new. The number of really invaluable drugs is certainly very small, but it includes digitalis. Digitalis has been studied at length by many investigators and its mode of action has been fairly definitely established. Of its dosage less is satisfactorily known. Different samples of the leaf and different preparations vary enormously in their potency and much effort has been devoted to the problem of finding a means of standardization. Of the standards proposed, the "cat unit" of Hatcher is becoming accepted as the most reliable for translation into dosage for man. The cat unit, it may be explained, is "that amount of the drug which is just sufficient to kill one kilogram of cat when slowly and continuously injected into the vein. This is expressed in terms of milligrams of the drug, whether it be a pure principle or the leaf."

Following this method of standardization Eggleston (*Archives Int. Med.*, 1915, xvi, 1) has determined, in a series of cardiac cases, the amount of the drug which has proved necessary to produce "full therapeutic or minor toxic action." He emphasizes the desirability of using a preparation which has been standardized by the cat method, but states that if such is not obtainable it is safe to proceed on the basis that a high-grade leaf has an average cat unit strength of 100 mg. He concludes that "the average therapeutic dose of digitalis, given orally to man in the form of the tincture or infusion, is 0.146 cat unit or about 0.146 c.c. of an average high-grade tincture per pound of body weight." Likewise 0.066 cat unit, or 0.023 mg. per pound is the average therapeutic dose of crystalline digitoxin. In his cases the majority did not vary 15 per cent. above or below this average. The chief drawbacks of digitalis therapy have been first, that it developed its action rather slowly and second, that the stomach not infrequently became intolerant to the drug before the desired therapeutic result could be attained.

Eggleston proposes the following method of administration which he claims will largely overcome these disadvantages. The dose for the patient is estimated on the basis of one-seventh of a cubic centimeter of a high grade tincture for each pound of the body weight. In estimating this dose it is necessary to estimate and disregard the proportion of the patient's weight, which is due to edema as well as that due to fat in the very obese. One-third to one-half of this dose is given at once and followed, in four to six hours, by one-quarter to one-third the dose. The remainder is to be given in smaller amounts at intervals of from four to six hours. If, after the total dose has been given, the patient fails to show the full therapeutic effect, administration of small amounts should be continued until such effect appears. Given in this way, the full effects of the drug may be manifest in from twelve to thirty-six hours in the majority of cases. Eggleston says that the large amounts of digitalis given early do not cause gastric irritation since he has given from 5 to 15 c.c. repeatedly and has never seen the least disturbance as a result. Indeed, when it is realized that the vomiting of digitalis is a result of its central action it will seem probable that large amounts may be given in this way before the onset of nausea. It is, of course, understood that this method is for cases of acute cardiac decompensation and is not designed to supplant the so-called chronic digitalis therapy which is followed in the less urgent cases. He states that both digitalis and digitoxin are probably rapidly and fairly uniformly absorbed from the alimentary canal of man, but digitalis is less completely absorbed than is digitoxin. Strophanthus, strophanthin, ouabain, and true digitalin, on the other hand, are poorly and irregularly absorbed when given by mouth and are unsuited for therapeutic use in this way.

CASTELLANI'S COMBINED VACCINATION.

ONE of the most signal advances recently made in the prophylactic use of vaccines is Castellani's method of combined vaccination which is now being used on an extensive scale in France and Italy. This method is based upon the experiments conducted in Kruse's laboratory in 1901 and 1902 by Aldo Castellani, who showed that if an animal is inoculated with three different species of bacteria the quantity of agglutinins and antibodies elaborated in its blood corresponding to each species is equal to the amount that would be produced if this species alone were injected.

The results of his latest work on this theme are reported by Castellani in *Lo Sperimentale*, July 14, 1915. He states that in the experimental animal which he has employed, namely, the rabbit, it is not possible to obtain regularly good results with more than three species of bacteria. In man, however, satisfactory results are apparently obtained with four species of microorganisms, and in certain instances even with a greater number. Ten different combinations of vaccines have been prepared for prophylactic use. They are the following: (1) Typhoid + paratyphoid A + paratyphoid B. (2) Typhoid + Malta fever. (3) Typhoid + para-

typhoid A + paratyphoid B + Malta fever. (4) Typhoid + paratyphoid A + paratyphoid B + *Bacillus asiaticus* + *Bacillus columbensis*. (5) Typhoid + paratyphoid A + paratyphoid B + *Bacillus asiaticus* + *Bacillus columbensis* + Malta fever. (6) Typhoid + paratyphoid A + paratyphoid B + dysentery (Shiga-Kruse) + dysentery (His Y) + dysentery (Flexner type No. 1) + dysentery (Flexner type No. 2). (7) Cholera + bubonic plague. (8) Cholera + typhoid + paratyphoid A + paratyphoid B. (9) Cholera + bubonic plague + typhoid + paratyphoid A + paratyphoid B. (10) Cholera + bubonic plague + typhoid + paratyphoid A + paratyphoid B + Malta fever.

The inoculation of any of the above vaccines into a human being is harmless. The reaction is not a severe one excepting in the case of the vaccines containing the plague bacillus. These give a reaction more intense than that produced by the simple antipest vaccine of Lustig and Galeotti, but less than that produced by Haffkine's antipest vaccine. The combined vaccines are prepared from agar cultures in the form of emulsions in physiological salt solution with the addition of one-half of one per cent. of phenol. Such an emulsion gives a less intense reaction than one in which the microorganisms are killed by heat. Twenty-four hours suffice for the destructive action of the phenol. The typhoid + paratyphoid A + paratyphoid B vaccine may also be prepared by heating the broth cultures to 53° C.

Individuals inoculated with mixtures containing as many as four species of bacteria produce in general agglutinins for each species, and the quantity in each instance is not much less than if a simple "monovaccine" has been employed. In the case of vaccines containing more than four species of microorganisms some give satisfactory results and some do not, the agglutinins developing for certain species of the bacteria and not for the others. The vaccines which Castellani has found of most practical value are the typhoid + paratyphoid A + paratyphoid B vaccine introduced by him in 1905; the cholera + bubonic plague vaccine; the typhoid + paratyphoid A + paratyphoid B + Malta fever vaccine; and the typhoid + paratyphoid A + paratyphoid B + cholera vaccine. The use of these combined vaccines has obvious advantages over the use of the separate simple vaccines, particularly in dealing with the large aggregations of individuals in armies.

THE WASTE OF LIFE.

In Europe, at the present time, life is being wasted on a scale never before witnessed in the history of the world. But it is not only in war that life is wasted, for it is being wasted all the time when the ordinary routine of existence is being pursued. In the *Popular Science Monthly* for July, 1915, this subject is discussed by Elaine Goodale Eastman, and although the matter has been pretty well threshed out during the past few years it is important enough to bear repetition. The writer pertinently says that the death rate among young children is actually a touchstone of community welfare; a test of civilization. A high rate of infant mortality means individual ignorance and social injustice. As for the causes of high infant mortality, these are attributed to the mother's condition before and during the birth, as affected by alcoholism, social disease, and overwork. There is also lack of proper care during confinement. According to Mangold, in American cities about one-half of the births are attended by midwives, 90 per cent. of whom are inefficient. The next greatest cause is lack of maternal nursing. It has been estimated that as many as 70 per cent. of the infants in New York City are bottle fed, a fruitful cause of infant mortality. A third leading cause is the use of impure milk.

The remedy for this state of affairs, the writer thinks, should consist in an active propaganda among women concerning the importance of maternal nursing. Emphasis should be laid upon the dangers and inconvenience of artificial feeding. Let it be thoroughly understood that bottle feeding is a grave misfortune if unavoidable, and if avoidable an unnatural wrong. It is pointed out that New Zealand has the lowest rate of infant mortality in the world, and this result has been brought about mainly through the activity of volunteer societies.

The writer does not refer to the most important work of this description, the schools for expectant mothers and mothers. Such schools were first established in Belgium and France and then in Great Britain, and in the large cities of all these countries. They have done magnificent service in reducing infant mortality and improving the physical and mental condition of poor children. American cities are now beginning to recognize the menace of child destruction, and many of them are engaged in what is known as a "Baby Saving Campaign." The program of a "Baby Saving Campaign" is somewhat of this nature: (1) Insistence upon complete and prompt birth registration as a basis of work. (2) Rigid inspection of the milk supply, with frequent tests for fat content as well as for dirt and bacteria. Recognized grades of wholesome milk include (*a*) certified milk; (*b*) inspected milk; (*c*) pasteurized milk. (3) The establishment of pure milk stations, where such milk may be obtained at or below cost, and to mothers unable to pay the price may be furnished free. Such milk must be supplied only on proof of inability to nurse the child, if too young for proper weaning. (4) Baby clinics and the employment of trained nurses to visit the homes, especially of the very poor, to care for sick babies, and to instruct mothers in the care of infants. (5) Improvement of bad housing conditions, warfare against flies and the breeding of flies, and general educational work.

THE HEMOPLEUROPNEUMONIC SYNDROME.

The study of a large number of cases of penetrating wounds of the chest during the first six months of the present war has enabled M. Piéry, of the medical faculty of Lyons, to delineate a condition to which he applies the above name. In the *Presse*

Médicale, June 3, 1915, he describes the characteristics of this syndrome as observed in fifty-three cases. The essential elements are a pneumonia combined with a hemothorax. The physical signs are said to be characteristic: on auscultation there is tubular breathing at the level of the middle of the lung; there is dullness or flatness on percussion at the base; radiography reveals a shadow which diminishes gradually from the base to the apex, and on aspiration of the pleural cavity there is obtained a bloody fluid. The symptoms are hemoptysis, sudden dyspnea which tends to diminish; moderate tachycardia, and a temperature curve exactly similar to that of pneumonia. Characteristic features are the recurrent rises of temperature and the slow resolution.

The above picture is frequently complicated by the presence of a slight or severe degree of pneumothorax; or by a secondary suppuration in the pleural cavity, which phenomenon is accompanied by a new rise in the temperature which assumes an oscillating character, and by a change in the character of the pleural fluid. Rare complications are caries or latent fractures of the ribs; collections of fluid in the mediastinum; wounds involving both the thorax and abdomen, and general pyemia with abscess of the lung and infective myocarditis. The treatment of simple cases of wounds of the lungs comprises whatever antirevulsive measures would be demanded by a case of pneumonia, and excludes, above all, operative intervention. The hemothorax particularly is to be let alone and the extraction of projectiles from the thoracic wall is to be delayed as long as possible.

The description of the above syndrome is an excellent instance of the manner in which, amid the turmoil of war, it is possible for the clinician to apply his mind in the study of problems of disease that are presented on a larger scale than during times of peace.

American Limb Prosthesis and the War.

The quality of the work done by our artificial limb makers is not half as well known among us as it deserves to be, although the subject has received full recognition in the successive editions of the "Reference Handbook of Medical Sciences." One of our leading manufacturers was also once selected to contribute the article on limb prosthesis for a German surgical system, and the excellence of the work done here is often made the subject of comment in Germany. At a meeting last April of the Royal Imperial Medical Society of Vienna (*Berliner klinische Wochenschrift*, May 31) von Eiselsberg presented a subject who eight years before in America had had amputation of all four extremities as a result of gangrene following very severe electrical burns. The amputations were made respectively in the continuity of the upper arms and legs. The man after six months' practice in exercising the stumps was supplied with four artificial limbs by an American manufacturer. He became able then to earn his living; could walk without a limp and had covered, without a cane, 18 kilometers (11¼ miles) in a day; was able to dress and undress, and feed himself and in fact seemed to show no great incapacity. He had been shown, for the moral effect, to the local soldiers who had lost their limbs in battle and it was proposed to exhibit him for the same purpose in the other military hospitals. As we noted recently, a society has been formed by Americans in Paris to supply the crippled French soldiers with artificial limbs made in this country.

The Ubiquitous Uterus.

In all lands and all ages the source of life has been the subject of human speculation, and this interest attaches to everything connected therewith. It is not surprising then that the uterus has always received more than its share of attention from medical writers. Before this organ had ever been studied in what we nowadays would call a scientific spirit there were hosts of theories, traditions, and legends about its anatomy, physiology, and pathology. The most widely held view of its nature and functions was that it moved about the body of its own volition, thereby causing the various disorders grouped under hysteria, which disease as is well known gets its name from the Greek word for uterus. For instance, the globus hystericus was due to the pressure of the vagrant uterus on the throat. Much as this idea may amuse us to-day it is hardly stranger than are the facts in the case when we compare the uterus at full term with the non-gravid one. A concrete illustration of the present-day appeal of this subject can be found by consulting the nineteenth volume of the second series of the index catalogue of the Surgeon General's Library, which has appeared recently. This book is devoted to the letter U, and no less than 291 of its 674 pages are filled with references to articles on the uterus!

News of the Week.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, M.D., 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the receipt of the following contributions for the week ending August 14, 1915:

Dr. W. L. Keller, Hot Springs, Ark.	$5.00
Dr. E. C. Ellett, Memphis, Tenn.	10.00
Dr. David W. Cheever, Boston, Mass.	20.00
Receipts for the week ending August 14	$35.00
Previously reported receipts	7,779.84
Total receipts	$7,814.84
Total disbursements	7,310.04
Balance	$504.80

The American Red Cross in Italy has sent out an appeal for aid from Americans, in order that the work of the society may not be impeded by lack of co-operation from its friends here. It is stated that the American colony in Florence, which is the central base hospital city of Italy, is equipping and will maintain a convalescent home for soldiers, for which supplies from America are urgently needed.

Serum Treatment of Wounds in the French Army.—A report from Paris announces that a number of remarkable cures have been effected by the new polyvalent serum, the discovery of which was announced last March. Complete recovery is announced of men who were terribly mutilated and for whom all hope had been given up before the serum was employed, so badly infected were their wounds. Drs. Leclanché and Vallée, the discoverers of the serum, have been unable up to the present to make more than 2,000 flasks of it daily, most of which goes to the base hospitals, where the worst cases are to be found. It is hoped, however, that it

can soon be made in sufficient quantities to supply the firing line, where it could be used prophylatically as antitetanus serum is now.

Germany's Loss Through the "Lusitania" Massacre.—The following note from Mr. Francis Potter is published in the *New York Times* of August 12: "I see that in the new German music hall song glorifying the sinking of the *Lusitania* the name of the late Alfred Vanderbilt is coupled with that of Sir Edward Grey, Germany's arch enemy, according to her publicists. It may interest the German public to know, through your columns, that Mr. Vanderbilt sailed for Europe with the intention of giving a very large sum of money to the Red Cross of the Allies and the Austro-Germans. Naturally, his death put a stop to the realization of this project and many wounded men of the Teutonic forces will suffer and perhaps die who might have been spared both suffering and death had Mr. Vanderbilt been spared to complete his plans."

Charitable Bequests Lost Through the Mexican Troubles.—In the will of the late Dr. Frederick S. Pearson of Great Barrington, Mass., who was killed on the *Lusitania*, bequests were made of $500,000 to Tuft's College and $50,000 each to the Home of Mercy Hospital, Pittsfield, and the General Hospital, Lowell. The estate, however, consisted largely of investments in Mexico, which have so depreciated that no funds are available for the payment of those legacies.

New York City Death Rate.—During the week ending August 7 there were 1,451 deaths in New York City; during the corresponding week of last year the deaths numbered 1,314; the death rates were 13.04 and 12.28 respectively, and for the week ending July 31, 11.94. The rate for the first thirty-two weeks of 1915 was 13.78, compared with 14.57 for the corresponding period of 1914.

Chicago Death Rate.—During the week ending August 7 there were 535 deaths in Chicago, compared with 615 during the corresponding week of 1914; the death rates were 11.4 and 13.4 respectively, and for the week ending July 31, 10.4.

A Case of Bubonic Plague in California.—The California State Board of Health reports the death of a man in Contra Costa County from bubonic plague. This is said to be the first death from this disease which has occurred in California since October, 1913. The man is believed to have contracted the plague from ground squirrels, many of which are known to be infected with the disease.

An Epidemic of Typhoid Fever has prevailed during the past three weeks at the boys' reformatory and branch workhouse on Hart's Island, New York City. There have been over sixty cases. The outbreak is believed to be due to the presence of two carriers, one a cook, the other a waiter in the workhouse.

Accident Service at the Norwegian Hospital.—Owing to the great influx of manufacturers into the district along the water front of South Brooklyn during the past fifteen years, there has been a marked increase in the work of the accident and emergency department of the Norwegian Hospital, the number of calls averaging about ten a day, or over 3,000 a year. For this reason the Board of Managers announce a portion of the addition to the hospital, now in course of construction, will be devoted to a special accident department.

Dr. Andrew J. Gilmour of this city has succeeded, in company with Professor Helvey of Excelsior Union, in scaling Mount Geike, one of the highest and steepest peaks in the Selkirk range of the Canadian Rockies. This is the first time, as far as known, that the summit of the mountain has ever been reached.

Dr. George W. Alexander of Gardiner has been appointed medical examiner of Kennebec County, Maine. He is a native of Prince Edward's Island and is a graduate of the medical department of Georgetown University, Washington.

Physicians Must Pay Postage.—The Health Department of Minneapolis has hitherto supplied the physicians of that city with stamped envelopes for use in reporting births and deaths. This is regarded, however, as a needless expense by the city fathers, who happen just now to be on economy bent, and accordingly they propose to cut out the appropriation for postage from the health department budget for 1916.

New Oregon Physicians.—At the recent State Board examinations in Oregon, 30 out of the 49 candidates received licenses to practise medicine. Of 11 osteopaths who applied for licenses 9 were successful. The Board of Medical Examiners consists of Dr. Charles T. Chamberlain, president; Dr. L. L. H. Hamilton, secretary; Dr. Herbert S. Nichols, treasurer, and Dr. Harry F. McKay, H. L. Henderson, and F. E. Moore.

A Collective Investigation of Twilight Sleep.—Dr. A. J. Rongy, 62 West 89th street, New York, writes that, on request, he has undertaken a study of "twilight sleep" the results of which will be presented at the next annual meeting of the Association of American Obstetricians and Gynecologists. He is desirous of obtaining all the available statistics on the subject and has prepared a set of questions which he will be glad to send to any one who has had any experience with this obstetrical method and is willing to favor him with the results of such experience.

American Electrotherapeutic Association.—The twenty-fifth annual meeting of this association will be held at Atlantic City, N. J., September 14, 15, and 16, 1915, with headquarters at the Hotel Chalfonte under the presidency of Dr. John W. Torbett of Marlin, Texas. All physicians interested in physiotherapy are invited to attend. The secretary of the association is Dr. J. Willard Travell, 27 East 11th street, New York City.

American Association for Study and Prevention of Infant Mortality.—The sixth annual meeting of this association will be held in Philadelphia, November 10-12, 1915. The subjects to be discussed include: Eugenics; effect of the economic standing of the family on infant mortality; infant welfare nursing in small cities, towns, and rural districts; institutional mortality; midwifery conditions, and treatment and prevention of respiratory diseases. Mr. Homer Folks of New York is president of the association, and Dr. S. McC. Hamill of Philadelphia president-elect for 1916. Dr. Joseph S. Neff, 801 Weightman Building, Philadelphia, is chairman of the Committee on Local Arrangements. The sessions will be under the chairmanship of the following: Eugenics, Dr. Wm. F. Snow, New York City; Pediatrics, Dr. Charles A. Fife, Philadelphia; Obstetrics, Dr. Mary Sherwood, Baltimore; Economic Aspects of Infant Welfare, Mr. Sherman Kingsley, Chicago; Nursing and Social Work, Miss Ella Phillips Crandall, New York City. The session on Economic Aspects of Infant Welfare will be a joint one with the Philadelphia County Medical So-

ciety and will be held at the College of Physicians. All other sessions will take place at the Bellevue-Stratford Hotel. Programs or other information in regard to the meeting can be secured from the executive secretary, Miss Gertrude B. Knipp, 1211 Cathedral street, Baltimore, Md.

Obituary Notes.—Dr. ARTHUR T. HILLS, formerly of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1875, a member of the American Medical Association and the New York State and County Medical Societies, and consulting surgeon to the Metropolitan Hospital, Blackwell's Island, died at St. Joseph's Hospital, Nashua, N. H., on August 7, aged 64 years.

Dr. CHARLES HARVEY SHATTUCK of Everett, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1881, died at his home on July 26, aged 57 years.

Dr. WILLIAM J. HAMLON of Mt. Carmel, Pa., died at Philadelphia on July 11 as a result of nephritis at the age of 55 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1895.

Dr. CHARLES CARROLL O'BRION of Groveton, N. H., a graduate of the Medical School of Maine, Portland, in 1881, and a member of the New Hampshire and Coos County Medical Societies, died at his home on July 16, aged 66 years.

Dr. JOHN WESLEY GRESHAM of Jackson, Tenn., a graduate of the Kentucky School of Medicine, Louisville, in 1895, and a member of the American Medical Association, the Tennessee State Medical Association, and the Madison County Medical Society, died at his home, after a brief illness, on July 16, aged 40 years.

Dr. JOHN H. MAHAN of Memphis, Tenn., a graduate of the Memphis Hospital Medical College in 1896, and for twenty years in charge of the Memphis City Hospital, died at St. Joseph's Hospital, Memphis, on July 19, aged 55 years.

Dr. MERRILL E. DAWSON, formerly of Otsego, Ohio, a graduate of the Cleveland College of Physicians and Surgeons in 1895, died from drowning on July 18, on his farm at Loranger, La., aged 51 years.

Dr. CORTLAND KIERNAN HAND of Mt. Vernon, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1914, died at his home on July 30, aged 23 years.

Dr. WINFIELD BECK SHEPHERD died at Philadelphia on July 13 at the age of 30 years. He was graduated from the University of Michigan, Department of Medicine and Surgery, in the class of 1910, and he had served as intern in the Samaritan Hospital.

Dr. EDWARD BEDLOE died at the Samaritan Hospital, Philadelphia, on July 24 at the age of 67 years. He was graduated from Jefferson Medical College in the class of 1869 and from the Pennsylvania College of Dental Surgery in the class of 1870. He was at different times United Consul at Verona, Italy; Alexandria, Egypt, and Amoy and Canton, China.

Dr. DAVID R. UMSTEAD of Philadelphia, died of heart disease at Wildwood, N. J., on July 25 at the age of 57 years. He was graduated from Hahnemann Hospital and Medical College in the class of 1878.

Dr. J. KINNIER CRAWFORD died of uremia at Philadelphia on August 1 at the age of 48 years. He was graduated from Jefferson Medical College in the class of 1894.

Correspondence.

THE MENACE OF CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Since my name and work are mentioned in them, I venture to claim the courtesy of the insertion of a few remarks in your pages upon the interesting series of articles on the menace of cancer in your issue of July 3, 1915. I note in your leading article the significant words: "Surgical treatment nevertheless does not afford an absolute cure, and herein lies the weakness of the contention that cancer in its early stages, or at any stage, is a purely local disease." Practically the same thing is said (p. 12) by Dr. Duncan Bulkley, who certainly from his professional position ought to know the truth or falsity of this. Coming from the quarters it does, that weighty medical statement would be a sufficient justification, were any needed, for any attempts of mine to throw scientific light upon the nature and rational treatment of cancer. In your article you speak of the problems of the "nature and origin of the disease," about which I shall presently have something to say. But first of all allow me to refer to general scientific principles in the treatment of cancer or any other disease. On p. 41 of the same issue is a statement, by Dr. Brem of Los Angeles, to the effect that the cerebral type of malignant malaria "does not recover"—that is, is incurable. Certainly this may well be true, so long as in its treatment no scientific principles underlying malaria be taken into account, but, strange to say, my friend, Major F. W. Lamballe, of the Royal Army Medical Corps, has demonstrated (Case XII) in the pages of MEDICAL RECORD (November 22, 1913), that the "severe cerebral type" with double infection *is curable*, and in a very easy fashion, provided the scientific general principles and their consequence, laid down by me, also in your pages (MEDICAL RECORD, March 29, 1913), be followed. The like is true of tuberculosis, as well as of many other things, but, notwithstanding the striking results obtained in the pancreatic treatment of tuberculosis by Baetzner and Major Lamballe, not many days ago I had to inform a correspondent, in reply to a query, that I did not know of anyone else within one hundred miles of Edinburgh, who was treating tuberculosis *scientifically*. With equal truth I might have written within five thousand miles. Now, sir, I am about to make an assertion, the truth or falsity of which can be proved readily by the answers given by your readers to a simple question. Notwithstanding all the talk there is about "medical science," the medical profession as a whole has not yet grasped the scientific general principles underlying the practice of medicine when attempting to deal with the ravages of microorganisms and cancer. I assume, by the way, that they have not seen the solution of the question, which I intend to give very shortly, after stating it.

Only a few weeks ago I put this question to a physician, a former pupil, in practice in this city. His reply was prompt, brief, and decisive. It was in the words, "Hanged if I know." To this I said, "the answer is very simple." But first of all let us state the question, which every medical man ought to have put to himself long ago. It is: "Why do certain microorganisms, such as the tubercle bacillus, the parasite, or antisite as I should prefer to term it, of malaria, the cancer-

cell, *et hoc genus omne*, attack the human body?" "Hanged if I know," says each and every one of your readers! The scientific reply was as follows: The microorganisms of disease (including the cancer-cell) attack the human body, pulling down the compounds making up this, because these organisms (and the cancer-cell) are themselves made up of compounds, including albumins, of opposite stereochemical constitution to those making up the human body. It is owing to this antithesis in stereochemical constitution that these organisms produce (intracellular) ferments or enzymes of opposite stereochemical constitution to those found normally in the human body, especially in the pancreas. It is this production of enzymes of opposite rotation, that is, opposite stereochemical constitution, which enables these organisms, including the cancer-cell, to attack the living laevo-rotatory albumins of the human body and to pull them down, inverting the products for their own purposes. It follows, by the way, inevitably from this conclusion, that the only rational, that is, scientific method of meeting and defeating the attacks of such organisms, including the cancer-cell, is the employment of genuine pancreatic ferments, trypsin and amylopsin, of great purity and potency. If I be asked for the production of the evidences establishing the scientific validity of these conclusion, it must be obvious, that in the limits of a letter these cannot be given. Nor is it necessary that they should be. They have been produced already by me in the pages of the MEDICAL RECORD of former years. References to all the papers concerned will be found either in Beard, "The Enzyme Treatment of Cancer," London, 1911, Chatto & Windus, or in a paper by me entitled, "On the Occurrence of Dextro-Rotatory Albumins in Organic Nature," MEDICAL RECORD, March 29, 1913.

It is most remarkable that, although many of the fundamental facts regarding these stereochemical compounds were described by that genius Pasteur so long ago as 1860, and although Duclaux said that with Pasteur chemistry had taken possession of medicine, these facts and the additional ones discovered by me have not had the slightest influence upon medical practice. For all the use made of stereochemistry in clinical medicine it might, as before 1860, have no existence! I suppose that one may say that medical men are very careful, as is mankind in general without knowing much or even anything at all about it, to see that their patients receive nourishment of the proper stereochemical constitution! They do not, for example, recommend a laevo-rotatory sugar, such as laevulose, because they know, instinctively or chemically, that such a compound would have no food-value, even if it were not a rank poison to the human body. But they never trouble themselves about the stereochemical constitution, or the rotation, of any of the remedies which they employ against the microorganims of disease. Why it should ever be expected that such remedies, as for example quinine, should be efficacious agents when employed against the microorganisms of disease is, scientifically regarded, not in the least clear. Why, for instance, should it for a moment be supposed, that in nature there is, under the name of quinine, an absolute specific for malignant malaria? no one can give any reason at all why quinine should be a specific for malaria, or how it acts upon the organism of malaria. On the other hand, my researches have demonstrated not only that trypsin and amylopsin in combination are bound to attack and kill the organism of malignant malaria, even in cerebral cases, but also how and why these ferments do this without injury to the living human patient. All the same, quinine is still regarded as a specific for malaria, even by those who sometimes instead employ methylene-blue! Years ago I was informed by more than one scientific man that in tropical medicine there were, as is the case with cancer, no vested interests concerned. My actual experience has been that this assertion was mythical. Vested interests are present in both, and in reality in both they are the same in kind. They are not the love of money, but they are due to the innate stupidity of human nature and its intense dislike of the new and the strange.

Returning to the menace of cancer, all the essential facts regarding the nature, treatment, and cure of this in suitable cases, as is also true of tuberculosis, malignant malaria, etc., are now known. In nature cancer and these other things are asexual generations, of opposite stereochemical constitution to the organism they attack, and for all of them, and many more such things, the proper, that is the scientific treatment is the employment in the form of hypodermic or intramuscular injections of the pancreatic ferments, trypsin and amylopsin. It does not matter how long, whether decades or centuries, official research into cancer, tuberculosis, or malaria goes on, no other scientific solutions of the problems they present will ever be found. For in fact there can possibly be no other scientific solutions. On p. 14 of the MEDICAL RECORD of July 3, 1915, Dr. Harrower once again assigns to me, quite erroneously, the "trypsin" treatment of cancer. I have never employed the term "trypsin treatment," and, indeed, times without number I have repudiated the authorship of it. What in 1905, first of all, I did urge was the use of "the secretion of that important digestive gland, the pancreas," including both trypsin and amylopsin, and later on I was enabled to state, that injections of trypsin and amylopsin in combination should be the agents employed, as also in tuberculosis and malaria. Ten years ago no suitable injections of either trypsin or amylopsin were upon the market, and, as a fact, it took me seven years to obtain for the years to come injections which would in my scientific opinion meet all the requirements. In their latest and best shape the preparations of Messrs. Fairchild Bros. & Foster have the form of a dry powder, which will keep indefinately in any climate, and which can be dissolved for injection in a few minutes. But now, that at last adequate preparations are on sale, and at remarkably cheap prices, now that the scientific requirements have been met fully, the medical people have no use for them. These preparations are at least twenty times as powerful as those first put out in 1906, while they are infinitely more potent than certain other preparations largely used in that year and later on. But why should I trouble to argue the thing at length? Scientifically, one does not need to reduce the statistics of the deaths from cancer, as Dr. Harrower would appear to suppose, in order to demonstrate the scientific truth of the statement, that a cure, the cure, for cancer has been discovered. The reasons why seemingly the treatment failed when first enunciated were threefold, viz., the hopeless nature of the cases selected, the inadequacy of the preparations first used, and the wrong methods in which the preparations were

employed. All the same, as the pages of the MEDICAL RECORD bear witness, the very first Fairchild preparations did cure a few cases of cancer. The scientific treatment and cure of cancer, or malaria, or tuberculosis are of the nature of a chemical experiment, and, being such, a single positive result carries with it, scientifically, conviction. A single successful case is of the nature of what Pasteur termed "a crucial test."

Though these are not his exact words, Professor Emil Fischer is often quoted as having laid down the thesis, that "a ferment fits the substance upon which it acts as a key fits a lock." In the MEDICAL RECORD of March 29, 1913, I cited his exact words and showed what he had proved. Rightly, he regarded his thesis as fully established by setting up two experiments and their positive results. The first experiment was needed scientifically in order to establish the fact, the second merely to confirm it. There was no occasion for any alteration in statistics, or in anything else in this universe, after that to establish the eternal truth of his thesis. Some of the cured cases of cancer are described, with the published references, in my book, "The Enzyme Treatment of Cancer," and in the form of a single case of round-celled sarcoma, with microphotograph of a section of the tumor before treatment, with photographs of the patient and other details, the "crucial test" of the scientific truth of all my theses regarding cancer, its nature and treatment, was offered to the whole world. An invitation was there given to any medical man to inspect all the evidences, including the charts of the case, but to this day not a single medical man has ever expressed the slightest wish to see any of these evidences, which are still in my possession. No, Sir, like the Royal Army Medical Corps, although one of its members some two years ago showed his colleagues in their own journal how relapse malaria could be cured easily, quickly, and cheaply, and which chooses to invalid soldiers suffering from relapse malaria in France home to India, the medical profession prefers its own antiquated views concerning cancer, malaria, tuberculosis, etc., because otherwise it would need to learn something new. A scientific knowledge of cancer, tuberculosis, malaria, etc., postulates some acquaintance with embryology and stereochemistry. These sciences, in my experience, are not taught to medical students, or if they are taught, it is not as they should be taught. Until embryology is regarded and taught as one of the most important courses in medical study, and until a knowledge of the elements of stereochemistry, as established by the researches of Pasteur, Emil Fischer, and myself, comes to be looked upon as essential for the medical man to possess, it is quite hopeless to expect to see further advances made in the direction of curing cancer, tuberculosis, or even malignant malaria. For there are none so blind as those who deliberately shut their eyes to truth and refuse to recognize its existence.

J. BEARD.

8 BARNTON TERRACE, EDINBURGH.

Splanchnoptosis and Gastric Acidity.—E. P. Sandrock finds that in ptotic stomachs there is a general tendency toward diminished acidity and that hypochlorhydria, and achylia are more frequently met with than hyperchlorhydria, the ratio being about 2 to 1. Cases complicated by marked atony give a still higher degree of diminished acidity.—*Bulletin of the Johns Hopkins Hospital.*

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ORGANIZATION OF RESEARCH—CANCER—ARTIFICIAL LIMBS—SIR J. FRENCH ON THE MEDICAL SERVICES—HOSPITAL SATURDAY FUND—DENTAL ASSOCIATION—MORTALITY OF WOUNDED IN WAR—THE KING GEORGE HOSPITAL—DR. MURRAY AND THE OXFORD DICTIONARY—THE LATE MR. OWEN.

LONDON, July 30, 1915.

A NEW scheme for the organization and development of research has been issued through the Board of Education. It is not to supersede or interfere with the War Office, Admiralty or other ministerial arrangements, but is to be a responsible body for assisting research with a single fund for the whole kingdom. It provides for a committee of the Privy Council responsible for the expenditure of moneys granted by Parliament for research and, further, for a small advisory council responsible to the committee and composed mainly of eminent scientists and men engaged in industries dependent on scientific research. The primary function of this advisory council will be to report on proposals for instituting researches or for establishing or developing existing facilities for scientific study of problems connected with industries in relation to awards of studentships and fellowships in research.

The Council will keep in close touch with all Government departments interested in research and particularly with the National Physical Laboratory. It will act in cooperation also with the Royal Society and other scientific and professional institutions. The general principle on which grants are to be made is that discoveries made shall be available under proper conditions for the public advantage. An annual report is to be made and presented to Parliament. Office accommodation and staff will be provided by the Board of Education.

The Cancer Research Fund has had its annual meeting of the General Committee. The report shows that four members of the staff are on active service with the R. A. M. C., which has curtailed largely the work of the research laboratories. Two Japanese gentlemen, who had been conducting researches in Germany, came to this country on the outbreak of the war and have been at work in connection with the fund and are now carrying on investigations in the laboratories.

During the year animals inoculated with tumor have been supplied to professors in other laboratories at home and abroad in accordance with the practice of the fund to provide others with material for research. Dr. J. A. Murray, general superintendent, presented his report. In it he dealt with the factors determining (a) metastasis formation, (b) immunity, (c) biochemical problems.

The metastasic process consists of two phases—first, the passage of the tumor cells through the endothelial layer of the lymphatic or blood vessels in the primary focus, whether of a spontaneous or transplanted tumor. The second phase is separated by the mechanical transport and arrest of the intravascular emboli in sites remote from the primary focus. By intravenous inoculation the first phase factors are eliminated and the success or failure of growth is determined entirely by processes at the site of arrest. As to immunity, it has previously been shown that it has only been demonstrated against cancer grafts and the tumors arising from them, but there is no effect on spontaneous tumors.

Among the biochemical problems I may name the results of an investigation concerning the reaction of the medium on enzyme action communicated to the Royal Society by Dr. Compton before taking charge of a military bacteriological laboratory. Also Dr. Bullock's experiments showing that the autolytic ferment in the serum is responsible for the liberation of aminoacids by digestion of the serum proteins. He had completed these before leaving for service with the R. A. M. C.

The report concluded with a study of cancer founded on the report of the Registrar-General for 1913.

Sir Watson Cheyne, treasurer, said the subscriptions for the year had been rather less than in the previous year.

We have had an exhibition of artificial limbs organized by Queen Mary's Convalescent Auxiliary Hospital. At a conference in connection with it, among the speakers were Sir Watson Cheyne, Sir W. A. May and Surgeon-General Russell. They emphasized the importance of ensuring that men should be fitted at the earliest possible moment they were in condition for them and should be taught how to use them. A month's delay, Sir W. A. May declared, might throw the patient back a whole year. More than a thousand men are said to be now waiting, and it was decided that orthopedic surgeons should be asked to report on the type of limbs that should be supplied in view of the work to be done by the recipient while the question of how the necessary appliances could be obtained was also considered.

The Orthopedic Surgeon's Committee have awarded a gold and a silver medal for exhibits showing the chief advances in mechanical skill—a silver medal for the best general excellence. Gold and silver medals have yet to be awarded for the exhibit with mechanism best fulfilling the requirements of the soldier, taking expense into consideration. The conference has excited a good deal of public interest and among those present at the reception in connection with it were Queen Amélie, Princess Louise, and many well known leaders in society.

Sir John French in a recent dispatch says he has much pleasure in again expressing his warm appreciation of the admirable manner in which all branches of the medical service in the field have met and dealt with the many difficult situations resulting from the operations. The medical units at the front, he says, were frequently exposed to the enemy's fire and there were many casualties in the regimental medical service, but at all times their duties were carried on with fearless bravery and great devotion to the welfare of the sick and wounded. He adds that "the whole organization of the medical services reflects the highest credit on all concerned."

The Hospital Saturday Fund's receipts for the first half of the current year amounted to £12,253, being more than £1,000 above the same period last year.

At the annual meeting of the Dental Association Mr. Dolomore, President, dwelt on the disasters which follow neglect of the teeth, indications of which have been observed in the present war. Much was done by dental hospitals and practitioners at the outbreak of war, but voluntary effort was notable to cope with the emergency and the War Office tardily undertook the work, but did not appoint a committee with dentists on it who were able to advise. The need of special supervision was admitted and the knowledge of dentistry by the R. A. M. C. he pronounced nil. Perhaps that is a little too positive, as some have certainly exhibited considerable knowledge of it.

The death rate among our wounded has been high and in parliament Mr. Asquith had to admit a percentage of 24, though in the Crimean war it did not exceed 22 and in the Boer war 20. In the Franco-Prussian war the Germans only lost 17.53 per cent. With all the boasting about asepticism greater improvement might have been anticipated.

The King George Hospital is the largest in London for treating the wounded. It had been built for another purpose and was bought by the military authorities on the outbreak of the war, as it required scarcely any alterations and was completed and fitted up as a hospital. It consists of six floors, each extending over $1\frac{1}{2}$ acres of space. There are ten lifts; some can take patients lying down from the entrance direct into the wards. It is said there are nearly three miles of corridors. The wards vary in size from those of three beds to others of sixty-five. There is a roof garden with twenty-four revolving shelters. About fifty-five miles of electric wire have been laid and there are 3,500 electric lamps in the building.

Dr. James Murray, the chief editor of the Oxford Dictionary of the English language, died on Monday, aged 78. His health had failed for some time and an attack of pleurisy was the immediate cause of death. It was his hope to finish the dictionary by his eightieth year. He did not originate the dictionary, but when the scheme seemed to be a failure and practically abandoned he took it up and made it a success. When he began many slips of quotations had been lost but he appealed to readers to extract illustrative quotations. About 6,000,000 were collected and three years were spent in arranging them and a million are included in the work. It was reckoned in 1880 that ten years would suffice to complete a lexicon of 7000 pages, but it was not until 1883 that the first part of 352 pages was issued and more than three times the estimate have already gone through two additional editions. Drs. Bradley and Craigie have joined the staff and numerous assistants have been engaged. He made his the most authoritative dictionary ever produced, which will no doubt be the basis of any future work of the kind for the English language and which may well be the model of such works in other tongues.

Dr. Murray was Romanes lecturer at Oxford in 1900. He made a number of contributions to literature, of which the article "English Language," in the *Encyclopedia Britannica*, may be named. He received honorary degrees from several universities and was knighted in 1908. A civil list pension was awarded him in 1884.

Edmund Owen, F.R.C.S., LL.D., Chevalier of the Legion of Honor, died on the 23d inst., age 68, the result of a paralytic seizure on the 20th. He was consulting surgeon to St. Mary's Hospital and surgeon to the French and other hospitals; surgical examiner at the universities of London, Cambridge, and Durham, as well as the Royal College of Surgeons, to which he had been vice-president. He received honors from other universities and long enjoyed the position of distinguished authority on surgery and a leading practical hospital surgeon. Among contributions to surgical literature I may name that to the *Encyclopedia Britannica*.

1. The Treatment of Eczema, with Special Reference to the Use of Vaccine and the Part Played by Bacteria in Its Etiology. Report of Cases. L. S. Medalia.
2. Variations in the Sensory Threshold for Faradic Stimulation in Psychopathic Subjects. Manic Depressive Insanity. The Dementia Precox Group. G. P. Grabfield.

1. Vaccine Treatment of Eczema.—L. S. Medalia concludes that eczema in its primary stages is a dermatitis the exciting cause of which may be any external or internal irritant capable of exciting a dermatitis. The "necessary something" or the "unknown quantity" in the etiology referred to in the text books, responsible for changing the dermatitis into a true eczema is the secondary bacterial invasion of the dermatitis. The absence of bacteria in the primary or dermatitis stage of eczema and the abundant growth obtainable from the secondary or true eczema lesions, together with the clinical response to the autogenous vaccines are thought to substantiate the etiological relation of bacteria to this disease. *Staphylococcus aureus*, according to the author's findings, is the organism always present in eczema, at times mixed with the streptococcus and rarely mixed with the *Staphylococcus albus*. The general condition, food idiosyncrasies, habits, and occupation of each individual patient should be carefully studied in order to eliminate if possible the exciting causes of the dermatitic lesions. Ointments, powders, and other topical applications, though temporary in their effect, are necessary adjuncts to the vaccine treatment to protect the raw skin and help to relieve the patient's discomfort. The presence of the streptococcus should always be kept in mind and when found a separate autogenous vaccine should be prepared therefrom. The use of large doses—6000 million organisms or over—of the autogenous staphylococcus vaccine was found necessary for the successful treatment of this disease.

2. Faradic Stimulation in Psychopathic Subjects.—G. P. Grabfield selected twenty-five cases of manic-depressive insanity at random from the clinic of the Psychopathic Hospital, Boston. He found that the cases in the depressed phase show a decided raising of this threshold to definitely pathological values. This increase in the depressed cases falls to normal with the return to a normal emotional state. The cases in the manic phase show a normal or perhaps slightly lowered value for this threshold. The cases with hallucinations or delusions or both show when averaged a markedly higher threshold than the average of even the depressed cases. The average is obscured by the fact that it contains many nearly normal values obtained in manic cases. These symptoms, however, seem to indicate a more profound derangement of function, as the cases, whether manic or depressed, which showed them yielded the highest values in the group in which these cases fell. The impression that variations in the sensory threshold for faradic stimulation are of central origin (derived from work on normal subjects) seems to be borne out by this group. The suggestion is made that the manic-depressive syndrome may be due to a perversion of function of certain parts of the central nervous system, possibly the thalamic centers, and that, contrary to Kraepelin's view, the symptoms of mania and depression may be due to opposite perversions of function. The determination of the sensory threshold for faradism shows that pathological values are constantly obtained in only about one-third of the cases of dementia precox and hence that this determination is of diagnostic value only in this percentage of cases. The mechanism governing emotional tone in dementia precox appears by this test to be different from that which governs this phenomenon in manic-depressive insanity. The correlation of catatonic symptoms with high threshold values parallels the correlation between these symptoms and post-rolandic cortical lesions. From this it is probable that the "arrival platforms" for faradic stimuli lie in the post-rolandic region. The correlation between somatic delusions and high threshold values is evidence in favor of the suggestion that these delusions are associated with a perversion of the receptor mechanism.

10. Cystitis in Women. L. W. Bremerman.

1. Mouth Hygiene.—E. L. Fisk outlines this subject as follows: (1) Beginning in infancy, a thorough physical examination and survey at regular intervals, in order to detect any possible focus of infection or any physical impairment that may lead to the formation of such a focus. (2) The practice of personal hygiene all along the line, in order that the general resistance to infection may be raised to the highest power. (3) Proper diet in infancy, which means, wherever possible, mother's milk, in order that there may be a regular and healthy development of teeth and jaws. As the child grows older, the cultivation of normal eating habits, especially vigorous use of the jaws by thorough mastication and the eating of hard, resistant, crusty foods every day. (4) The use of fruit in the diet between meals, especially apples, which mechanically cleans the teeth, and which by the action of fruit acids removes the mucin plaques that favor decay. (5) A thorough mechanical cleansing of the teeth with clean water and stiff brush, used with a rotary motion, not forgetting the tongue. (6) Thorough dental cleansing of the teeth at least every six months. (7) If unfortunately dental decay has taken place, care on the part of the dentist thoroughly to treat infected roots, so that a septic focus may not be sealed in by a filling; in all cases of doubt, the use of the *x*-ray, in order to determine the condition of the roots. It is said that few people arrive at maturity without a chronic alveolar abscess. An *x*-ray of the jaws as a starter in mouth hygiene would be a wise precaution for every one. (8) The development of the teeth should be closely watched, and irregularities, interfering with proper contact between upper and lower teeth, corrected or prevented. The earlier this is done, the better for the patient. (9) Bearing in mind that the endamebas are possible factors in pyorrhea, a simple harmless preventive is available in a mouth wash made by adding two drops of fluid extract of ipecac to a half a glass of water, used before retiring. This will not be of any service in well established cases of pyorrhea, but in the earliest stages it may check the condition. (10) When pyorrhea has become fully established, no pains or expense should be spared in curing the condition, as it is a constant menace to life and health. Experience has shown that this disease can be cured by thorough and persistent treatment, if there has not been too much destruction of the tooth sockets. Where the teeth are hopelessly loosened and the sockets destroyed, it is often far better to remove them, just as it

is far better to extract an abscessed tooth rather than endanger the patient's condition by endeavoring to save it. It is better to lose a tooth than to lose a heart or a kidney. On the other hand, the tooth should not be ruthlessly extracted on the first suspicion of trouble. Common sense and a due sense of proportion are necessary in these matters.

5. Pyorrhea Alveolaris.—F. E. Stewart notes that Bass recommends the use of emetine hypodermically or intramuscularly in doses of one fourth to one grain, but states that it has been given by the rectum, also in keratin coated pills by the mouth. He also recommends the employment of the drug locally in the form of a one-half to one per cent. solution, injected by means of a hypodermic syringe deeply into the pyorrhea pockets. Each pocket is left filled with the solution as the needle is withdrawn. Bass recommends rinsing the mouth thoroughly with a solution of fluid extract of ipecac, two or three drops to a half a tumbler of water, which, he believes, protects against reinfection and actually cures the disease in its early stages. He believes that patients can carry out this treatment in many instances. The author advises the following routine treatment. Preceding the use of vaccines, emetine should be employed to destroy the amebas in the gums, dental tissues, and alveolar processes. The solution of emetine hydrochloride, 0.5 per cent. in strength, should be forced down into the pockets with a hypodermic syringe and each pocket left filled with the solution. This treatment should be repeated daily for three or four days. After the second or third injection, the gums should take on a more and more healthy appearance, the teeth should feel firmer, and the gums about them become tighter and harder. It may be unnecessary to employ vaccine treatment, in which case the operative procedures for obliterating the pus pockets may be all that is required in addition to the emetine treatment. But in chronic cases of pyorrhea alveolaris, not only are the tissues infected with bacteria, but in all probability the infected mouth has become a focus of infection to the entire system, in which event vaccine therapy may prove of great value not only in curing the local condition, but also in the restoration of the general health and in raising the resistance of the tissue to a higher plane, thus insuring against reinfection. A stock vaccine may be used, either sensitized or unsensitized, or an autogenous vaccine prepared from the pus pockets may be employed. It is considered good treatment to begin with a stock vaccine either sensitized or unsensitized, the former being preferable on account of the comparative ease with which it is digested and assimilated by the tissues, the freedom from local or general reaction, and its promptitude in stimulating immunity. If an autogenous vaccine is preferred, care should be taken to select an experienced bacteriologist for its preparation. If an unsensitized bacterin is employed, the initial dose advised is 150 million of the mixed bacteria; 250 to 750 million may be given as the initial dose if the sensitized cultures are employed. Subsequent doses are injected at intervals of seven to ten days, gradually increasing or decreasing according to indications. If the reactions are too severe, the doses should be reduced or temporarily discontinued. Every dose should be carefully gauged by the effect obtained from the preceding dose. If no improvement follows the initial dose, subsequent injections should be increased until amounts large enough to produce a mild clinical reaction (demonstrated by symptoms of malaise and possibly aggravation of the local symptoms) are reached. If a marked clinical reaction occurs after a dose, characterized by rising temperature, the next dose should be smaller.

7. A Form of Diabetic Coma Not Due to Acetone Bodies.—J. Rosenbloom studied the three cases of diabetic coma the interpretations of which differed completely from the modern idea of acidosis as the cause of coma. They were all of the severe type, with no tolerance for carbohydrate, and with a restricted protein intake there was no lessening of the glucose output. They were studied for a period which varied from one week to two months. During this time the urine contained a normal amount of ammonia-nitrogen and showed no trace of acetone, diacetic acid, or betaoxybutyric acid. There was no evidence of kidney disease. The urine contained excessive amounts of colloidal nitrogen, neutral sulphur, and aminoacids. Death occurred in typical diabetic coma. It might be held, however, that the acetone bodies were not excreted, but retained. In the last case studied 200 c.c. of blood were taken shortly before death. Only faint traces of acetone, diacetic acid, and betaoxybutyric were found. The nonprotein nitrogen of the blood serum was normal in amount. This case is especially interesting on account of the fact that about fifty hours before death, showers of granular casts were present in the urine. The urine was cloudy, owing to the presence of such an enormous number of casts. This finding has been described in typical acidosis coma. Rosenbloom found that an intravenous injection of 600 c.c. of 6 per cent. sodium bicarbonate produced a marked improvement in the symptoms.

3. Intestinal Obstruction.—G. H. Whipple studied the characteristics of the poison that acts in intestinal obstruction. It can be obtained from a fluid above an intestinal obstruction, from a closed washed loop of small intestine, or from the mucosa of a closed loop or one draining externally through an enterostomy wound. The intoxication varies only in intensity. One can inject this poison into a dog and produce more or less profound intoxication, according to the amount injected. Dogs can be immunized by sublethal doses, but the immunity cannot be carried very high. They can then survive intestinal obstruction or closed loop longer than the control dogs. Filtered, immune organ extracts, presumably containing active enzymes, can destroy the poison in vitro, but the blood of immune animals contains no such enzymes, and is inactive

toward the poison. The absorption of the poison is not from the lumen of the intestine, but from the mucous membrane which forms it and passes it into the blood, while the mucosa itself may seem almost normal. The chemical nature of the poison is not fully determined. Its proteose nature explains why the poison is held back in fine earthen filters, but not by paper filtration. It is not destroyed by digestion with pancreatin for a period of one week, and only with autolysis with intestinal mucosa after months. The author assumes that the intoxication from the closed intestinal loop is due in great measure to the absorption of a primary proteose from the intestinal mucosa. He has not been able to detect the substance in the urine, perhaps because the small amount is fatal, and the flow of urine is inhibited after a large dose. The proteose, too, may be changed in some manner before it is eliminated. Diuresis will help in the elimination, and this explains the good effects of salt infusions in intestinal obstruction.

7. **Botulism.**—By E. C. Dickson. (See MEDICAL RECORD, July 3, 1915, page 43.)

8. **Early Diagnosis of Mastoiditis.**—J. J. Kyle notes that abnormal temperature should disappear quickly after rupture or puncture of the drum membrane. If it persists, the mastoid is involved. Tenderness over the mastoid is not an infallible sign, though valuable. Pain in some region of the head on the affected side is usually present. The two most valuable signs are pulsating discharge from the middle ear and high temperature. Diagnosis of chronic mastoiditis is more difficult than that of acute. The destruction of bone may be all out of proportion to the clinical signs. The value of the Röntgen rays in the hands of an experienced man is beyond dispute.

15. **The Pineal Gland.**—C. P. McCord has performed a series of experiments in which evidence of the precocity of development usually attributed to pineal deficiency (hypopinealism) has been obtained in animals by supplying an increased amount of pineal substance by feeding or injecting pineal preparations. Such administration of pineal substances led to a more rapid growth of body than normal, and determined an early sexual maturity. The excess in rate of growth was most pronounced (40.9 per cent. excess in eleven weeks) in young animals fed with pineal tissue obtained from young animals. No tendency to gigantism has followed pineal administration. After maximum size was attained, pineal administration appeared to be ineffective. Both males and females responded to the influence of pineal substances in the rate of growth, but the response to the gland substance was more definitely manifested in males.

18. **Proteolytic Ferments in Portal Blood.**—F. H. Falls finds that the portal and peripheral blood of the dog contains a demonstrable increased amount of proteolytic ferment at the height of digestion. 2. This is also true of the portal blood in the dog in the fasting state. 3. Under both the foregoing conditions, the portal blood is relatively richer in ferment than the peripheral blood. 4. The probable source of this ferment is the ferment-rich intestinal contents at the height of digestion.

5. The Value of Turpentine as a Hemostatic. G. G. Turner.
6. The Signification of Acetone Bodies in the Urine. B. Derham.

1. **The Treatment of Wounds in War.**—Sir W. Watson Cheyne answers the recent adverse criticisms of the method which he has proposed, namely, the application to wounds of antiseptic pastes and powders following a thorough disinfection of the wounds; and cites reports of favorable results following the use of this method among the English wounded at the Dardanelles.

2. **New Methods in Treatment of Cholera.**—Sir Leonard Rogers states that in 1906 he first commenced giving physiological saline solutions in large amounts intravenously, and the mortality fell from 59 to 51.9 per cent., only to rise again in 1907 (when he was absent on leave) to 59.5 per cent. In 1908 he commenced the use of hypertonic salines intravenously, and the mortality at once fell to 32.6 per cent. On adding large quantities of permanganates by the mouth late in 1909, with a view to destroying the toxins in the bowel by oxidation, a further reduction in the mortality was obtained to 25.0 per cent in 1003 consecutive cases in the course of six years. During the last three years the mortality has been only 23.5 per cent. The author has also obtained favorable results with the routine use of intravenous and subcutaneous injections of alkalies in the prevention and treatment of postcholeraic uremia. He has also followed Brunton's suggestion that atropine should be used in cholera on the ground that it antagonizes the symptoms of muscarine poisoning which resemble to a considerable degree those of cholera. Doses of 1/100 grain were administered morning and evening to adults during the acute stage of the disease with the result that the death rate was reduced from 24 per cent to 10.7 per cent.

5. **Turpentine as a Hemostatic.**—G. G. Turner notes that the principal sphere of turpentine as a hemostatic is in cases of secondary hemorrhage. It has several times been successful when the ligature of one of the main vessels of a limb in continuity or even amputation seemed to be called for. The turpentine should not be applied until the area to be treated has been thoroughly freed of blood clot and débris, and though it is not always necessary to use an anesthetic for this purpose it is usually wiser to do so. When one is dealing with areas in which there are large vessels an attempt must always be made to secure both ends of the vessel in the wound according to the well-established rules for the treatment of secondary hemorrhage, but turpentine is especially valuable in those cases in which no bleeding point can be caught but in which the hemorrhage is nevertheless alarming.

9. A Further Contribution to the Diagnosis of Gout. J. B. Berkart.
10. The Care of the Illegitimate Baby. A. D. Fordyce.

1. **Poisoning by Noxious Gases.**—J. E. Black, E. T. Glenny, and J. W. McNee emphasize certain points in the clinical study of this condition. None of the cases remained in the casualty clearing station for more than five days after the inhalation of the gas. It is thus the acute stages only which are described. On admission the cases were of two chief classes: (1) the acute asphyxial and (2) the subacute. Of the first class almost one-quarter died. This class was characterized by orthopnea and marked cyanosis. The subacute cases, on the other hand, showed a dyspneic condition, never amounting to orthopnea, and were cyanosed to a lesser degree. Treatment of the acute asphyxial cases was unsatisfactory, which is not to be wondered at when considered along with the changes found in the lungs post mortem. The subacute type, however, responded well to treatment, and the cases, although distressed by constant coughing, all admitted the relief gained. The treatment found most satisfactory in such cases was the frequent administration of ammonium carbonate in full doses. The routine treatment evolved from the experience gained was: (1) Abundant supply of air and warmth. (2) An emetic of salt and water if the patient was very cyanosed and had not already vomited, followed by (3) the administration of ammonium carbonate, 15 grains, and wine of ipecac, 15 minims, every 3 hours. (4) Oxygen inhalation in cases of marked cyanosis and dyspnea. (5) Opium in doses of ½ to 1½ grains in restless cases to allay the mental strain. (6) Pituitary extract (1 cubic centimeter) and brandy when the heart threatened to fail.

7. **Movement of Diaphragm in Early Pulmonary Tuberculosis.**—H. Walsham and W. Overend note that the limitation in the descent of the diaphragm frequently occurring in the early stage of pulmonary tuberculosis, which phenomenon is known as Williams's sign, accompanies many other diseases of the lungs and pleura. The effect of this reflex must be a reduction in duration and amplitude of the ordinary inspiratory wave, and its object the attainment of a definite measure of rest and protection for the diseased area of the lung.

9. **The Diagnosis of Gout.**—J. B. Berkart describes a pathological process of frequent occurrence which gives rise to clinical phenomena closely similar to those commonly called a gouty paroxysm, but which is not due to uric acid. The habit of looking for the cause of the painful swelling to the surface of the joint has diverted attention from its other constituents. Yet if the corresponding bone be carefully examined, it will be found that very often take place within it, silently and almost imperceptibly, changes which in their last stages fully account for those symptoms. Such examination discloses in the first metatarsals, and occasionally also in the phalanges, a cystoid degeneration, which starts in the epiphysis, extends to the articular cartilage, and after perforating it allows the discharge of the cystic contents into the joint, thus producing an acute "perforative synovitis." The resulting fistulous openings are generally minute and readily escape detection, as do the cysts themselves so long as they are of small size and concealed by fat marrow. This cystoid degeneration originates from an anomaly of the vascular and osseous systems. Conspicuous among them is the abundance of dilated and thin-walled veins which are here and there studded with emigrated blood corpuscles. There is consequently evidence of a state of chronic congestion under the influence of which the trabeculæ are decalcified and the adjoining fat marrow becomes fibrous. The cystoid degeneration is readily distinguished from gout by the absence of swelling of the regional lymphatic glands. It may, however, become gouty if from a concomitant disease of the kidneys uric acid is retained and accumulates in the blood. The tissues, especially those of an inflammatory or a metaplastic nature, then undergo hyaline degeneration, and favor the deposition of uratic crystals. Such change in the type of the disease is then shown by the accession of the diagnostic element of gout—namely, the enlargement of the regional lymphatic glands, which have also become hyaline.

Berliner klinische Wochenschrift.

June 28, 1915.

Immunotherapy and Serotherapy of Typhoid Fever.—Meyer writes on the new or rather rejuvenated specific treatment of typhoid. We do not yet know how nature cures the latter. It can hardly be through the action of agglutinins alone, for those whose blood clumps the best often perish from the disease, and it can hardly be the bacteriolysins alone, because injection of highly bacteriolytic sera does not alter the course of the disease. The defence of nature must be complex, and this must also be true if improvement follows the injection of dead cultures such as are used for immunization. The author relates his experiences as follows: he gave immunizing injections to 300 healthy subjects who received in all 650 injections. As a rule a local or general reaction, when such developed, was mild. A pronounced general disturbance usually had a special reason. In two cases the patients had already had typhoid. This behavior suggested that in tuberculin inoculations of tuberculous subjects. In a number of other cases the individuals doubtless suffered from latent microbism and true typhoid was lighted up. Subjects with latent tuberculosis and influenza patients give pronounced reactions. In treating established typhoid with dead cultures a control material was necessary, so that another series of patients was treated symptomatically. In both series the disease was of a severe or very severe type and in many cases treatment was begun late. Naturally mild cases were not included in the statistics. The specific action of the cultures was quite apparent, but the mortality was nevertheless nearly 10 per cent gross; although this could be reduced to about 6 per cent net by leaving out hopeless cases. The mortality in the nonspecific series was nearly 20 per cent. gross. In the material as a whole the tendency to heart failure as a result of enormous hardships was very prominent, and all patients therefore received digitalis from the start. In both series the mortality among the early treated was much less than that of the late treated. The specific remedy is unable to manifest itself in the delayed cases. In the inoculated material there was but 5 per cent. of relapses as compared with the normal 13 per cent., and it seems very probable that those inoculated during convalescence have their chance for relapse greatly diminished. This also holds good for sequelæ. Convalescent serum of patients has been shown to possess notable specific virtues in the treatment of typhoid. Alstaedt writes in the same number of the *Wochenschrift* on typhoid immunity and reports attempts at establishing serodiagnostic reactions similar in character to those in use in tuberculosis and other specific infections. He showed that in subjects who in all probability have not been exposed to typhoid the intracutaneous reaction is negative; while if they have gone through the disease even many years before, the reaction remains positive. If either class of these patients is first immunized sensitiveness to this reaction is pronounced.

Insurance Medicine.

Life Insurance Medicine.—Emminghaus, late presiding director of the Gotha Life Insurance Bank, gives a number of his personal reminiscences in the capacity of director in the institution. When he first took charge, the organization of the administrative body had undergone no change since the foundation of the institution. There were usually three physicians in the bureau. Their functions do not seem to have been well defined but they seem occasionally to have submitted reports to the administrative officers of the nature of medical criticism.

At the outset the Bank had so-called "confidential" physicians in certain large cities. As a rule, the family physician made an attest as to the health of the applicant. If there were no family physician, others had to be called upon. As to just how the services of the latter were obtained we are not accurately informed. There was originally considerable difficulty in getting such men to act. Examinations had to be made, and opinions rendered. The chief duties of these examiners were bound up in the heredity, the personal history, etc., of applicants. These were the points which more especially required cleaning up, and involved the sincerity of the applicant.

When the author assumed his responsibilities, each agency was supposed to have its confidential examiner. At this period any ideas that life insurance could have a philanthropic side were out of the question. Since only the "healthy" were insurable, insurance was regarded very largely as a "gamble." That the enterprise could prosper without medical selection was not commonly understood.

From its very outset in Germany the medical man was regarded as an indispensable aid to life insurance. Hence only good risks were insured. Nevertheless, the sound applicant, so-called, might contain an element of hazard; and so it became apparent that within certain limits men not fully sound might be acceptable. Medical techniques were developed to extend the selection to substandard risks, whenever the latter could be brought on a par with standard risks. In this way, a new form of medical specialism was developed, which dealt with a standardization of risks.

This new component led to a wholesale extension of business, as a result of which new agencies, with their confidential examiners, were established. The latter were to be in close touch with the central authorities. In 1886, the author issued a small periodical for the benefit of the confidential examiners (Monatsblätter für die Herren Vertrauensärzte d. Gothaer Leb. Versicherungsbank), which movement in time reached its culmination in the publication of Florshütz's epoch-making work on Life Insurance Medicine. The periodical eventually became the *Blätter der Vertrauenärzte*.

The colossal data accumulated by the Bank were first utilized after the latter had completed its fiftieth year of existence (1829-1878). They were published in 1880 and contained five classes of statistics as follows: 1. Number applied, insured, rejected, lapsed. 2. Deaths. 3. State of insurance at completion of 50-year period. 4. Financial statistics. 5. Statistics of conditions of mortality.

Of especial significance for life insurance are sections 2 and 5, dealing, as they do, with mortality and its circumstances. Two quite different conditions were considered in the sections. The mortality *per se* was indicated in connection with occupation; cause of death; relations between results of medical entrance examination and cause of death; season of year; age and cause of death; duration of insurance; differences between expectation of life and actual mortality. In Section V, other material is introduced, as relation of insurance mortality to total mortality; special tables for sexes; statistics according to artificial age periods, and, in general, statistics based on combinations of the more elementary figures.

By analyzing the data of the five decennia of the fifty years it is readily seen that the mortality from tuberculosis had dwindled in the first two decades, although there had been no drop from 1849 to 1879. Cancer has steadily increased from the very outset. Inflammations of the chest increased three-fold as causes of death between 1829-1878. Apoplexy showed practically no variation during the entire period.

Hence since 1880 it has been possible, by a study of these figures, to secure a much better type of medical selection, although the organization of the medical personnel has undergone hardly any change.—*Blätter für Vertrauensärzte der Lebensversicherung*, March-April, 1915.

Some Court Rulings.—Giving a specified term of credit to an applicant for life insurance for payment of the first premium is held in Connecticut General L. Ins. Co. v. Mullen (C. C. A., 3rd C.) 43 L.R.A.(N.S.) 725, to waive a provision in the policy to the effect that it shall not take effect until the first premium is paid, while the applicant is in the same condition of health as described in the application.

Under an employer's indemnity insurance policy rendering the insurer liable for loss sustained by assured up to a specified sum for injury to a single employee, and providing that, in case the insurer elects to contest the claim, it shall pay in addition the expense of litigation and take charge of the defense at its own cost, the insurer is held in Aetna L. Ins. Co. v. Bowling Green Gaslight Co. (Ky.) 43 L.R.A.(N.S.) 1128, to be liable in case it does take charge of the defense and direct an appeal from an adverse judgment, instead of paying the specified sum and absolving itself, as it might have done, for the damages and interest on appeal and for the court costs, in addition to the principal sum specified and the expenses of the trial.

That as a portion of his treatment, an insured, under direction of his physician, sits out of doors a portion of the time, is held in Metropolitan Plate Glass & C. Ins. Co. v. Hawes (Ky.) 42 L.R.A.(N.S.) 700, not to destroy his rights under a sick benefit policy insuring him against sickness while he is wholly disabled and under the care of a physician for a period during which "he shall be continuously and necessarily confined to the house."

The Growth of Life Insurance.—In spite of the business depression due to the war and other causes in this country, it is stated that there was an increase of 15 per cent. in the volume of life insurance taken out in 1914 over that in 1913.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 11, 1915.

DR. WALTER LESTER CARR IN THE CHAIR.

Case Presentation.—Dr. HENRY HEIMAN presented an interesting case of a male child, 10 years of age, similar to one shown by Dr. Sara Welt-Kakels at Dr. Jacobi's monthly meeting. The family history of the patient was negative. She had had measles in childhood and had stumbled frequently while walking, since two years of age. The injuries received in these falls produced scars which were humerous on the elbows, knees, forehead, arms, and legs. Eleven days before her admission to the hospital in September she was seized with abdominal cramps, headache, and vomiting, and her temperature rose to 104° F. At the time of her admission to the hospital she had fever, and examination of her cardiac condition showed a systolic murmur at the apex. She had a maculo-papular eruption on portions of the body and on the palms of the hands and the soles of the feet. The lymph nodes were palpable; the extremities weak; knee jerks were absent, and there were no other abnormal reflexes. There was a left inguinal hernia. The blood count showed white blood corpuscles 5,800, polymorphonuclears, 86 per cent., mononuclears 2 per cent., basophiles 1 per cent. The fundi were negative as was also the von Pirquet test. The child was also examined by Dr. Abrahamson of the neurological service of Mount Sinai Hospital who found an internal hydrocephalus, a tendency to pes cavus, facial asymmetry, weakness of the left hand, and a tendency to fall to the left. Dr. Abrahamson thought the case was one of cerebellar diplegia with epileptiform tendency. Dr. Heiman regarded the case as a congenital trophic disturbance with maldevelopment of the tendons, skin, and muscles. When the skin was pulled it was elastic and rubber-like. These cases had been regarded as types of purpura, but had nothing in common with them. In this case there was no familial tendency as was shown in Dr. Welt-Kakels' case.

Dermatitis Bullosa Hereditaria.—Dr. SARA WELT-KAKELS presented the patient to which Dr. Heiman referred. This child showed a condition similar to that of the previous case. The only feature in which the cases differed was in the family history; Dr. Heiman's case showed nothing in the family history in any way connected with the condition, while in Dr. Welt-Kakels' case the father gave a history of hemophilia in his childhood which he had outgrown.

Dr. JOSEPH BYRNE stated that a case with the skin and muscle condition just shown had recently been presented before the Neurological Section. The man had traveled with Barnum and Bailey's circus as the "Boneless Wonder." His skin had the peculiar rubber-like quality referred to. Practice had enabled him to perform some wonderful feats; he could stretch the skin of the upper sternal region so that he could touch the forehead with it. In addition to the abnormal elasticity of the skin this patient exhibited marked hypotonia of the muscles of the legs, arms, and fingers, which enabled him to perform most weird contortions. This man had a defect in speech suggestive of paralysis of the soft palate, though there was no gross paralysis. The deep reflexes were said to be normal, if anything slightly exalted. There was some retardation in mentality. In crossing the knees he exhibited the overaction so frequently seen in tabes and allied conditions. This man had recently undergone a suprapubic cystotomy and there were no indications that he was a hemophiliac. Such a case occurring in a man over forty pointed to an unfavorable prognosis for the patients presented this evening, but perhaps lent support to the favorable prognosis given by Dr. Welt-Kakels as to the hemophilia.

Dr. HENRY HEIMAN said he could not agree with Dr. Welt-Kakels' diagnosis of dermatitis bullosa hereditaria, as this was observed usually on the feet, since they were exposed to friction and irritation causing blebs. He did not believe that any one could make a correct diagnosis at the present time. All that could be said was that these patients had trophic disturbances causing congenital maldevelopment involving the tendons, skin, and muscles.

Cases of Hemophilia, with Remarks on the Value of Blood in the Treatment of Hemorrhagic Diseases.—Dr. EDWARD W. PETERSON presented these cases, the one a boy and the other a girl, each six years of age. Both of these cases seemed to be true hemophilia; both showed severe post-hemorrhagic anemia. In both the hemorrhages recurred and the bleeding was finally overcome by blood from an outside donor, after the blood of the mother in one case and of the father in the other had resulted in only a temporary improvement. In such cases prophylactic doses of serum or blood should be administered every few months as in that way these children might be carried along, and it was well known that if one could tide over the period of puberty the tendency to bleeding decreased and might disappear altogether at maturity. Dr. Peterson quoted from Dr. Hartwell who held that, used with proper discretion in the conditions under consideration, blood transfusion had a real value. He also quoted from Dr. Crile to the effect that blood transfusion was a life-saving procedure when performed in accordance with proper indications; that the transfusion of homologous blood was a procedure analogous to the transplantation of living tissue; that it was followed by a rise in the number of red blood cells and an increase in antibacterial qualities, and that it was indicated in severe hemorrhages of all types, certain anemias unaccompanied by hemorrhage, and certain toxic conditions. It was always indicated when the source of the hemorrhage could not be controlled or removed. The plan followed was to take 20 to 30 c.c. of blood from the donor and at the same time an addition of 100 to 200 c.c. in order to get the serum that they might follow out Welch's method of administering 20 to 40 c.c. of the serum every six hours. If this failed they should resort to a second transfusion of whole blood. It was preferable, as indicated by the cases reported, to have a donor not related to the patient and to use unaltered blood.

Dr. GODFREY R. PISEK said that his personal experience in hemophilia had shown that it was necessary to give the blood injections serially, that was, in small doses at short intervals, particularly in cases that had previously been treated unsuccessfully by other methods; freedom from the repeated bleeding then followed.

Dr. ALFRED F. HESS said he believed they ought to make a distinction between purpura and hemophilia. In hemophilia the striking fact was the lengthened coagulation time of the blood, while in purpura the coagulation time was almost normal. Again, in purpura the platelet count was low; this was not the case in hemophilia. In every case one should examine the blood in reference to these two factors before deciding to which class of cases the one in question belonged. He felt inclined to consider the case of the female child presented by Dr. Peterson as a case of purpura, since hemophilia was exceedingly rare in the female. The other case might also be one of purpura since the diagnoses were not based on a study of the pathological conditions. Dr. Hess said he had recently seen a number of cases of both these conditions and had endeavored to control the bleeding with coagulose, fibrinogen, calcium, and gallic acid, and had finally succeeded with the emboplastic substance extracted from tissue. They had been working on this subject at the Research Laboratory and would be glad of the opportunity to try this preparation. They would be grateful if physicians seeing these cases would either try this themselves or refer the cases to the Laboratory.

Dr. PETERSON in closing the discussion, said he would not attempt to argue the question as to whether the cases were true hemophilia; Dr. Shamburg and Dr. Pisek had seen them and considered them hemophilia. The patients were both in a very critical condition, showing a high degree of anemia. In the girl there had been profuse epistaxis for a year and then purpura as a late symptom, while there could be no question in the case of the boy; almost from infancy he had shown a tendency to hemorrhage which was difficult to control.

The Use of Bismuth Pills in the Fluoroscopic Examination of the Infant's Stomach.—Dr. ALFRED F. HESS related his experience in attempting to measure the circumference of the pylorus by the ingestion of bismuth subnitrate pills coated with keratin, which would not dissolve in the stomach but would dissolve in the intestines. The pills were made in 9, 15, and 21 French scale. He had expected that the small pill would pass through the pylorus first and the larger one second, but he found that the large pill passed first. The No. 15 pill passed first; sometimes the two would pass together, but the smaller one never passed first. He then tried pills made of one-half bismuth and one-half lico-

rice, so that they would float in the stomach contents; here the same thing happened, the larger pill passing through the pylorus first. After ingestion of these pills the fluoroscope was the best instrument for observing them. One could see the pill move along the greater curvature. When the child was placed on the left side the pill would go to the left, and when on the right the pill would gravitate to the right. If the child was turned up-side-down the pill gravitated to the diaphragm. It was found that when the child was on the right side the pill left the stomach quickly; when on the left the pill went slowly. It seemed to the speaker that these observations might be made use of in cases of retention or of pyloric relaxation. Normally the pill left the stomach in from three to four hours; in some instances the time was a little longer. In cases of pylorospasm it required twelve to fourteen hours for the pill to pass the pylorus. Anesthesin had been given for the hypersensitiveness but it did not make much difference. Two centigrams of papaverin administered hypodermatically had proven more effective. In a dozen or more examinations he had found that whereas in pylorospasm the pills required from twelve to fourteen hours ordinarily to leave the stomach, after the administration of papaverin they passed in from three to four hours. Dr. Hess gave a lantern demonstration of radiographs which had been made by Dr. Gottlieb and called special attention to the enormous dilatation of the stomach in some of the cases and to the delay in the passage of the pills through the pylorus.

Dr. CHARLES GOTTLIEB said that the method which Dr. Hess proposed to determine the motility and the outline of the infant's stomach was interesting. It was easy to get the child to take the pills, whereas it had been very difficult to administer bismuth in suspension, and furthermore the children were liable to vomit the milk and spoil the picture. Even if they retained the bismuth so much gas resulted that it interfered with their observations. Dr. Gottlieb said that in his opinion, Dr. Hess had introduced a very useful method for determining the motility and position of the infant's stomach.

Dr. WILLIAM H. STEWART said that he had had no experience with the bismuth pills, but it was well known that babies had a tendency to empty the stomach of a body of large caliber before one of smaller size; this was because the larger body caused the greater irritation. One could not base any clinical observations on this fact, certainly no accurate knowledge of the size of the pylorus could be obtained by this method. It had been his practice to administer the bismuth meal by means of the catheter directly into the stomach; this gave a better opportunity of making accurate observations of the outline and motility of the stomach and he could not see that the proposed method offered any greater advantages.

Dr. GODFREY R. PISEK said that he was interested in Dr. Hess's remarks particularly from the standpoint of determination of motility. He could hardly agree, however, as to the practical application of this method in infants. The fact had been lost sight of that with the administration of a meal there was always distention of the stomach and that with the pill they did not get distention, and hence the conditions were not analogous. In his experience with different fluids and semisolids, the motility of the stomach varied; it also varied with the composition of the food, that was, whether the percentage of fats was high or low. The motility of the stomach also varied when the bismuth was given with water, alone, or in combination with different foods. Dr. Pisek said he merely wished to caution them in this respect. Dr. Hess had not made clear whether the caliber of the pylorus corresponded to that of the duodenal tube, which he understood was what the experiment set out to determine.

Dr. I. SETH HIRSCH said that though the knowledge of the exact size of the pylorus might be of value, still the expulsive power of the stomach had to be reckoned with. Even if there was a slight narrowing of the opening it did not necessarily follow that the stomach could not empty itself within the normal time. It was impossible to find this out with the bismuth pill. These observations made with the bismuth pill were none of them new; all had been made before. It was known that a large body passed through the pylorus faster than a smaller one and that the pylorus might be emptied faster with the patient on the right side. In fact this method was used by every roentgenologist in attempting to fill the duodenum. By the bismuth pills no observations could be made regarding the form, outline, shape, tone, or peristalsis. It was an error to infer from the varied expulsion of foreign bodies, as bismuth pills, that similar conditions occurred after the administration of food. In normal digestion the fluid portions were expelled first and the solid portions later. The conclusion reached regarding the effects of papaverin were not new. If a small dose of papaverin, from 1/50 to 1/75 of a grain, was given to a child with the bismuth meal in whom a previous examination showed a residue in the stomach at the end of four hours which created the suspicion of a pyloric stenosis, then if this stenosis was due to pure spasm, the stomach would be entirely empty four hours after the second meal, plus the drug, while if due to stenosis, the residue would be larger than that found with the first meal. Dr. Hirsch sounded a note of warning against the fallacy of drawing inferences from bismuth tests regarding the digestive time of certain foods in the stomach. Bismuth when suspended in the food showed a tendency to rapid sedimentation, which made the bismuth a foreign body more rapidly expelled than the food in which it was suspended. There was a method suggested by Kaestle of Munich which eliminated this error. Capsules of bismuth were used which were so made that one sank to the bottom and one floated on the surface of the fluid. By a serial roentgen examination of the patient one could determine how rapidly and when the stomach was empty by the observation that the capsules reached the same level and that it was possible to roll them about in the stomach.

Dr. ALFRED F. HESS, in closing the discussion, said that it was rather difficult to answer some of the questions that had been raised, for, whereas Dr. Pisek had doubted whether the same results would hold true where food instead of bismuth was given to the infant, Dr. Hirsch had stated that in adults it was an every day fact that food rapidly left the stomach and entered the duodenum when the patient was placed on the right side. It would seem that in view of Dr. Hirsch's large experience they must accept his statement and that Dr. Pisek's doubts would probably be found to have no substantial basis in fact. Dr. Hess said he hoped he had made it clear that the pills could not be used to determine the diameter of the pylorus, but were of value in the diagnosis of an obstruction at the pyloric orifice and that they showed this much more sharply than when the bismuth was given in milk, part of which frequently remained in the stomach, whereas the other part was seen in the intestines.

Treatment of Toxic Scarlet Fever with the Fresh Blood from Convalescent Patients.—Dr. ABRAHAM ZINGHER presented this paper. He stated that the donors were from three to six weeks convalescent from scarlet fever; in the majority of instances syphilis had been excluded by the Wassermann test and a careful examination was made to exclude tuberculosis. The method which he had employed consisted in inserting a medium sized platinum needle (No. 18 gauge and 1½ inches in length) into the vein of the donor and with a 30 c.c. Record syringe rapidly aspirating from eight to twelve ounces of blood, which was quickly injected into the muscles of the patient. The needle in the donor's vein was not removed, but a steel needle (No. 16 gauge and 1½ inches long was quickly attached to the syringe and the syringe full of blood was rapidly injected. In the meantime an assistant attached a smaller syringe containing some 1 per cent. sodium citrate to the needle in the donor's veins, to keep it free of blood. The large Record syringe should be rinsed out once or twice with the 1 per cent. solution of sodium citrate during the transfer of the blood. In a child a syringeful of blood was injected into each arm (triceps) and one into each thigh (vastus externua). In an adult two such injections could be made into each arm and thigh. If larger quantities of blood were to be injected the gluteal regions, the calves, and the deltoid muscles might be chosen. The injections were painless except for the slight discomfort associated with the entrance of the needle. No local reaction followed and the blood appeared to be rapidly absorbed. Nine patients suffering from severe forms of toxic or sentic diphtheria were treated at the Willard Parker Hospital with amounts of convalescent blood varying from three to eight ounces. In some of the patients there was a striking critical drop in the temperature within from twelve to twenty-four hours after the injection; there was also a distinct improvement in the pulse and general condition of the patient. The delirium in three of the cases cleared up very

rapidly and there was a slight improvement in the exudate on the tonsils and fauces. One patient treated with citrated blood (0.33 per cent. citrate from three convalescent donors showed a distinct improvement in the general condition, but the temperature continued for a few days from a complicating streptococcus exudate. The remaining two patients died from the complicating advanced septic condition. Cultures of the blood in both these cases showed the presence of a streptococcus. One of the two cases had received 2½ ounces, and the other 5 ounces of convalescent blood. It seemed, therefore, that in the later septic cases, where possibly the toxic scarlet fever element had disappeared from the clinical aspect of the case, these medium quantities of convalescent blood had much less action. Gland, joint, and ear lesions were not influenced. Larger quantities of fresh normal blood exerted a distinct beneficial effect on the disease especially when injections of from six to ten ounces of blood were repeated about three times at intervals of three to four days. Dr. Zingher said he hoped to be able to continue the work using moderate quantities of convalescent blood (4 ounces in children and 8 in adults) in the early and toxic cases, and larger and repeated injections of fresh normal blood in the later and septic stages of the disease. The use of citrated convalescent blood (0.33 per cent. sodium citrate) obtained by adding to 2.5 c.c. of a 10 per cent. solution to 75 c.c. of blood) would perhaps be a little more convenient to some and offered, in addition, the advantage of injecting blood from several convalescent donors into one patient. It also enabled one to have a supply of convalescent blood on hand. Such citrated blood could also be shipped to distant places. The effect of the sodium citrate, however, would have to be carefully determined; again, there was a tendency for the blood to deteriorate with time. Reiss and Jungman and R. Koch had used intravenous injections of large quantities of convalescent blood serum (50 to 100 c.c.) in toxic cases of scarlet fever. Their charts showed the same striking critical drop in temperature. But in obtaining serum fully 60 per cent. of the blood was wasted, and the blood could not be had in such abundance even when scarlet fever was most prevalent. They used the blood from those in an early stage of convalescence, from the eighteenth to the twenty-fourth day. It was quite possible that even two to three month convalescents could be used.

Dr. Matthias Nicoll, Jr., said that this idea of treatment was not new, but Dr. Zingher deserved credit for having invented a new technique in the giving of whole blood. The most promising field for its use was in the early toxic stages of the disease. He had not been much impressed, however, thus far in the septic cases of scarlet fever with enlarged glands and discharge from the nose and mouth. In two of the early toxic cases which he had observed the results of this treatment had been striking. The use of citrated blood in the one case he had observed produced little or no apparent effect so that this procedure would seem to be largely restricted to hospital cases in which convalescents could be obtained as donors.

Dr. William H. Park said that in reference to the citrated blood there certainly was no evidence that antibodies were injured by such a small amount for such a period of time. He did not agree with Dr. Nicoll that one-third of one per cent. of sodium citrate prevented the action of the serum. As to the clinical results of this method of treating scarlet fever, his observations agreed with those of Dr. Zingher.

Dr. William Shannon said that he had seen all the cases and was of the opinion that the serum had a decided effect upon the patients, which was indicated not only by a drop in temperature and the character of the pulse, but by the general condition of the patient. The results were less noticeable in the septic than in the toxic cases. In one instance the temperature fell after twenty-four hours but the patient got worse. A second dose of the serum was given and after twenty-four hours the patient showed a decided improvement, and this patient appeared septic. The cases reported did not strike him as being of a particularly toxic type. This plan of treatment was worth a more continued trial.

Dr. Louis Fischer related the case of a child eighteen months of age with diphtheria of the septic type. The child was admitted to the Willard Parker Hospital and treated in the usual way. The child's temperature was 105° F. and pulse 180; later in the afternoon the pulse came down to 156. The case was complicated with suppurative pleurisy. The prognesis seemed hopeless, and as a last resort eight ounces of citrated blood were administered. He had been especially impressed with the facility with which the injection was made into the median basilic vein. Within a few minutes the color of the cheeks improved, the lips and finger nails assumed a pinkish hue, and the cold extremities became warmer. Three-quarters of an hour after the injection the prognosis seemed more hopeful. The simplicity of the technique would adapt this form of treatment to secondary anemias, especially those following malnutrition.

Dr. Abraham Zingher, in concluding the discussion, said the paper was rather for the purpose of presenting a simplified rapid method for the administration of fresh convalescent blood and fresh normal blood than for the purpose of drawing definite conclusions as to the value of such treatment. The results, however, were very encouraging and seemed to justify a continuation of this treatment. The intramuscular injection of fresh whole blood taken from normal individuals would suggest itself also as a convenient and readily applied procedure in the treatment of surgical hemorrhages. Dr. Zingher had treated a case of typhoid fever, complicated by diphtheria, in which there was constant oozing from the nasopharynx after the separation of the membrane. Five ounces of fresh whole blood injected intramuscularly promptly stopped the bleeding, whereas the previous use of horse serum had no effect. He was glad Dr. Peterson endorsed the intramuscular injections of fresh blood in the treatment of hemophilia.

Tracheobronchial Diphtheria and Its Treatment.—Dr. Henry Lowndes Lynah gave this demonstration of his direct method of intubation, in which he used a small bivalve speculum and a small bronchoscope. He then gave a lantern slide exhibition showing direct views of the larynx in diphtheria, and demonstrating that the diphtheritic membrane sometimes spread downward through the trachea and bronchi as well as upward. Such cases of diphtheria had been passing unrecognized, being taken for bronchopneumonia. By this method it was possible to remove the diphtheritic membrane in pieces as well as other foreign bodies that might become lodged in the bronchi. The youngest child that he had intubated by this method was two weeks old.

Dr. William P. Northrup said that Dr. Lynah's demonstration appeared to him to have opened a new chapter in the knowledge of diphtheria and the lesions it occasioned.

Dr. Sidney Yankhauer said that his idea was that where the larynx was involved the laryngoscope could be used; in the intratracheal cases he had used the uterine dilator and passed the stem in that way. The direct laryngoscope was of interest to the pediatrician and he ought to be able to use it as it was the only method that could be used by the physician in which no assistance was required. It could be used in children as young as eight or ten months for the purpose of removing foreign bodies, and there was no other method by which the larynx could be seen in such young children.

Dr. Godfrey R. Pisek said that this work was of direct value to the pediatrician. Dr. Lynah's work should give them an impetus to study this type of cases and should impress upon them the importance of bearing in mind the possibility of tracheal and bronchial diphtheria and thus they might be able to save some cases that otherwise would be fatal. Personally he had seen such cases with physical signs that indicated a blocking sometimes of the right and sometimes of the left bronchus; the collapse was so complete as to simulate fluid. A prompt diagnosis, removal of the mechanical obstruction, and intravenous injections, offered some hope, as Dr. Lynah had been successful in a number of cases.

Dr. William H. Park related the case of an adult, admitted to the Willard Parker hospital from another hospital in which they were unable to decide whether the patient had asthma or diphtheria. They waited eight hours and then gave antitoxin. Death ensued in a short time and it was supposed that the man had died from serum sickness. Autopsy showed a diphtheritic membrane beginning at the larynx and extending down into the bronchi. An examination by Dr. Lynah's method at the general hospital would have revealed the condition at a time when life could have been saved. In the later subacute pneumonias one did not find the diphtheritic membrane.

Dr. Matthias Nicoll, Jr., said Dr. Lynah's work spoke for itself, but he had not done justice to the

value of bronchoscopy as a means of saving life in tracheobronchial diphtheria. Dr. Nicoll said he had seen a number of cases coming to autopsy in which the diphtheritic membrane extended even to the finest bronchi, but he did not recall such a case in which there was not also masked bronchopneumonia.

Dr. Henry Lowndes Lynah said that out of a series of 27 cases of tracheobronchial diphtheria 13 had died and 14 had recovered. Nine of the 13 deaths occurred shortly after admission to the hospital and were beyond help at the time of admission. If they could get these cases during the first two or three days they got very good results. Too much could not be expected from antitoxin in these cases as death was the result of the mechanical obstruction rather than of the diphtheria.

Stated Meeting, Held March 11, 1915.

Dr. Walter Lester Carr in the Chair.

Demonstration of a Simple Syringe Method for the Transfusion of Citrated Blood in Children.—Dr. Abraham Zingher gave this demonstration. (See Medical Record, March 13, 1915, page 440.)

Dr. William H. Park said he had seen Dr. Zingher perform the removal and injection of blood by this method and everything went smoothly and quickly. The method was easy to master and was suitable for those who wished to inject blood in young children.

The Pathology of Tuberculosis in Children.—Dr. F. H. Bartlett read this paper. He presented an analysis of 178 autopsies, at the Babies' Hospital, New York City, in which tuberculous lesions were found. A study of the earlier records of the hospital showed 16.4 per cent. tuberculous cases among 1,131 autopsies. The contrast with adult percentages was very striking, whether one accepted Lubarsch's figures, 69.2 per cent., or those of Naegeli, 93.1 per cent., as the average. The age incidence of this series varied from two and one-half months to five years, 75 per cent.of the subjects being under two years of age. It was interesting to note that in only five cases was the tuberculosis limited to the bronchial lymph nodes alone, and in only one to the mesenteric lymph nodes alone. The writer concluded that in children the primary infection of the lung was the usual mode of infection, since 82 per cent. of their cases were of this type. The absence of tuberculous lesions in the lungs in fourteen cases and the presence of such lesions in the bronchial lymph nodes in seven of these seemed to show that it was possible for the tubercle bacilli to pass through the lungs without localizing there. The largest number of cases were of inhalation origin, as shown by the large percentage of cases in which the pulmonary lesions were the most advanced in the body. The marked tendency to rapid and general dissemination of tuberculous lesions in young infants under one year of age was well shown. In view of this fact the survival of any young infant infected with tuberculosis for more than six months after infection was very remote, while healing of tuberculous lesions in young infants was practically out of the question. In the entire series not a single healed tuberculous lesion was found, and attempts at healing as shown by calcified areas were observed in only five instances in the lungs and thirteen times in the lymph nodes. Only twice was it found in infants less than a year old, and in both these cases the extensive generalization of the tubercles throughout the body gave evidence that the small calcareous areas present did not prevent spreading of the infection. Encapsulation of a tuberculous lesion was not encountered in this series of cases. The predominance of respiratory over deglutition infection was indirect evidence of the quality of the milk supply, though it should not be forgotten that children might carry tubercle bacilli into their mouths by their fingers infected from other sources than their food. The comparative frequency of tuberculous meningitis in young infants was noteworthy as evidence of the very general dissemination of tuberculous lesions in young subjects. In this series of 178 cases the meninges were found to be involved in 96 instances. The younger the infant the greater was the liability to meningeal involvement, or indeed to all forms of dissemination. One infant two and one-half months of age was found to have ten viscera involved in the tuberculous process. There was a smaller proportion of cases of tuberculous meningitis among children who acquired the disease by ingestion than among those who acquired it by inhalation, and this was in keeping with the fact that the cases infected through ingestion showed rather less tendency to generalization than did the respiratory cases. In the infant, tuberculous meningitis was a miliary tuberculosis and tuberculosis of the lungs was a miliary tuberculosis.

The Transmission of Tuberculosis in Childhood.—Dr. William H. Park read this paper, in which he first considered the infection of the fetus during intrauterine life and concluded that the evidence demonstrated that intrauterine infection occurred occasionally, but accounted for only a very small proportion of the tuberculosis of childhood. In most of such cases the mother had an extensive miliary tuberculosis. The conclusion that intrauterine infection never proceeded from the father seemed well founded. A very large amount of information on this subject had been gathered from cattle. Calves born of tuberculous cows were seldom infected when removed at the time of birth from their parents and fed on milk from uninfected cows or on that which had been rendered safe from tuberculosis by heating. The human infant after birth was endangered not only by bacilli from human sources, but from diseased cattle. It had been definitely proven that both types of tubercle bacilli were capable of infecting human beings from infancy through childhood. As was well known, cows only contaminated milk extensively when they had disease of the udder. When lesions in this region were extensive, many millions of tubercle bacilli might pass into each centimeter of milk. Ordinarily, however, only a few hundred bacilli were present in a cubic centimeter. One or two cows with seriously diseased udders were capable of infecting the mixed milk of a whole herd. It had been shown by a number of investigators that even when the udder was apparently normal a few bacilli might be found in the milk. It was possible that the bacilli might enter the milk in indirect ways from infected cattle. At present the raw milk supply of New York City was small in amount and was entirely from tuberculin tested cattle, and these tests, which had been previously made annually, were now made semi-annually. If either annual or semi-annual tests were carried out carefully, and no infected cattle were brought into the herds, few or no tuberculous cattle would be present in the herds, and those would very seldom have any dangerous involvement. During the past year a little less than five per cent. of the cows in the certified herds of Manhattan and Brooklyn had reacted, and on autopsy only about one-half per cent. of these reacting cows had more than a slight localized tuberculosis. None of the cows had any detectable udder tuberculosis. Quite a large number of samples from these herds had been injected into guinea pigs without causing any infection. Although it was impossible to state that the milk from the certified herds under present conditions was absolutely free of tubercle bacilli, still they were so few as to rarely, if ever, cause infection. The only sure method of getting exact facts was to test out the type of bacilli in every infected infant or young child who was fed on raw milk. The Health Department would be glad to do this in any material submitted if the type of milk and other information needed was given. The farms producing Grade A Raw Milk, which were not certified, were probably supplying a milk nearly as free from tubercle bacilli as the certified milk, though the supervision of these farms had not been as thorough as that of the certified ones. It was safe to say that where tubercle bacilli contained in milk were actually heated to 140° F. and held at that temperature for 20 minutes they were destroyed. If any escaped they were too few to infect animals. An investigation of the experiments that seemed to show that some bacilli escaped destruction during pasteurization revealed the fact that the method of testing had allowed bacilli on the surface of the milk to be exposed to a lower degree of heat. The evidence that butter actually transmitted tuberculosis was less direct than in the case of milk. Whether meat from tuberculous cattle had ever transmitted tuberculosis to human beings was still a question of some doubt. When the meat was thoroughly cooked all the tubercle bacilli were certainly killed; when it was rare some might escape. The evidence was clear that the majority of infections came from one human being to another. While bovine infection was most prevalent in early childhood, the human infection increased in amount up to fifteen years of age. It was interesting to note that, as in the case of many other diseases, infants, as a rule, possessed a considerable insusceptibility to tuberculosis. The figures did not bear out Behring's suggestion uttered in 1903 that the origin

of consumption was laid in infancy, remaining latent until something impaired resistance. Nor did their present knowledge agree with his belief that the original tubercle bacilli were usually of the bovine type. In the case of infants and young children the greatest danger lay in being attended by a tuberculous mother or nurse. The avoidance of this direct human contamination could probably only be thoroughly maintained by the entire removal of the infant or child from contact with tuberculous persons. The danger could, however, be greatly lessened if all possible precautions were taken, but probably these could never be so thorough as to eliminate danger. In some investigations that he had carried out, Dr. Park found to a striking degree that the children of tuberculous parents were more infected with clinical tuberculosis than those living in families where no tuberculosis existed. This was in accord with the results obtained by many. The interesting question as to whether the infection producing the later manifestations took place in adults or was the development of earlier infection had not yet been decided. If in this country adults did not become infected, it must be because they had developed and retained immunity through having an earlier infection or because they were naturally immune. They were certainly not yet in a position to be willing to subject children to infection with tubercle bacilli of either the human or bovine type in order that they have conferred on them a partial or possible immunity. This most interesting question of whether there was any way to safely protect from serious infection would undoubtedly be subjected to much study in the next few years.

The Recognition of the Fact and the Estimation of the Danger of Bovine Tuberculosis.—Dr. HENRY L. COIT of Newark, N. J., presented this communication, in which he stated that he had had no practical experience with or experimental knowledge of bovine tuberculosis. Many physicians were latterly making diagnoses of bovine tuberculosis in a loose and thoughtless manner. If there was a lymphadenitis, an exudative peritonitis, or a bone lesion, the infection was assumed to be of the bovine type. This drift was unwise and unwarranted. The tuberculous cow, possibly potential for danger, always had been and still was in the herds giving out milk supply, but to what extent she was a menace to the health of the child, or whether this danger was negligible, they were only just beginning to determine. The finding of a large number of tuberculous reactors in a well-guarded herd was a grave problem for the Medical Milk Commission, and had accentuated interest in the medical control of milk intended for clinical purposes, and not only the profession but the public had been awakened to its importance. It was not just that the discovery of reactors in a supervised herd should disturb the confidence of the people in the system of supervision of the certified milk supply, because all herds when tested and retested at some time showed their respective percentage of reactors. The Milk Commission, through its system of safeguarding the milk, had imposed sixty-five requirements upon the dairyman, only one of which in the present instance was called into question. For two years past many animals which did not react to the test before purchase did react in a few months in a well-guarded herd. This was presumptive evidence that they might have been rendered immune to the test by the surreptitious use of tuberculin before they were offered for sale. The Bureau of Animal Industry had estimated that at least 20 to 30 per cent. of all dairy cows in the United States were tuberculous. In view of this fact, the real difficulty was that they could not enforce upon breeders and dealers in cows sold for dairy purposes the unfailing duty of burning a branding mark in the hides of animals, whenever, upon the injection of tuberculin, they were found to be reactors. With this provision of law bovine tuberculosis could be efficiently and quickly stamped out as was contagious pluero-pneumonia a few years ago by the United States Government. Dr. Coit related the history of the attempt to gain the cooperation of the United States Bureau of Animal Industry in applying the tuberculin tests, which ended in failure. The Government refused to grant this help to an organized philanthropy like the Milk Commission, though spending thousands of dollars every year in testing the cattle of private parties. The desultory testing of herds by the Government conferred but one-half the benefit which would be accomplished were such testing done in conjunction with the Milk Commission. The speaker said he had no confidence in legislation or in the press as a means of solving the problems involved. To meet the fact of bovine tuberculosis required: (1) Effective organization of the controlling agency which should consist of non-political commissions with legislative authority, including in their membership medical, veterinary, and sanitary authorities of recognized ability, their work to be financed by State funds. The Medical Milk Commission was the pioneer in this field. (2) The fact should be met by dependable inspection and tuberculinization of the herds used for milking purposes by men of the grade of teachers in the veterinary schools, men of unassailable character. (3) It should be met by the invariable use of reliable tuberculin, such as that made in the laboratories of universities, or in State or Federal experiment stations. (4) It should be met by instituting the custom among high grade dairymen of breeding their own stock and thus avoid the danger of replenishing their herds from miscellaneous lots of cattle not free from tuberculosis. (5) The fact of bovine tuberculosis must be met by the systematic tests of all animals before purchase, and retests at stated intervals, with the segregation of all cows which showed any suspicion of reaction. The technique of the United States Bureau of Animal Industry should be followed in making the tests, with the filing of a report of all tests and retests with the authority in charge of the work. Dr. Coit expressed the opinion that while he did not minimize the importance of bovine infection in young children or the great importance of having the milk herds absolutely free from reactors, yet he believed in the improbability of the frequent presence of live tubercle bacilli in milk from well-guarded herds in which good dairy hygiene was practised. The probability of transfer of bovine tuberculosis through milk, under present conditions, was very small. The medical profession and the public were menaced by a bacillus far more vicious and virulent than the tubercle bacillus. Its name was "Commercialism." The wonder was that the public and a part of the medical profession were so gullible and could not interpret these trade practices or recognize their true character.

The Care of the Tuberculous Child.—Dr. I. OGDEN WOODRUFF presented this communication. He called attention to the change that had come over their ideas of tuberculosis in childhood during the last ten or fifteen years. Formerly tuberculosis in childhood was looked upon as a disease seen but little outside of a hospital and one in which the discussion of treatment was of a value more academic than practical, but more recently attention had been drawn to the prevalence and frequency of tuberculosis in childhood. The author concerned himself more particularly with the consideration of cases of the early and hopeful type and with prophylactic measures. The most important preliminary step was the making of an accurate diagnosis and here familiarity with tuberculosis as seen in the adult was of little value in aiding one to detect the disease in the child. When it came to treatment they pinned their faith on the same trio which were the mainstays in the adult, rest, fresh air, and superalimentation. Rest should be particularly emphasized. It was the impression of the speaker that it was not generally given the attention it deserved in children. The fact that the nutrition of the child did not suffer to a serious extent in early tuberculosis, and readily responded when the amount of food was increased and the appetite stimulated by change in environment, the absence of fever by mouth temperature in early and even moderately advanced cases, and the appearance of rapid improvement, tended to throw one off his guard as to the importance of rest. In the child the pulse was particularly susceptible, and it was his custom to use it as a guide to the amount of exercise in which a child might with safety indulge. The pulse and temperature should be noted before exercise and one hour afterward, and the work graduated according to its effect. The child should be kept mentally satisfied with quiet occupations. Schooling in the fresh air might be permitted for three hours daily. For cases in the quiescent or apparently arrested stage postural and breathing exercises exerted a marked benefit. From the climatic standpoint the one particularly bad combination was heat and humidity. As to diet, high caloric foods were indicated until the weight was normal or slightly above it. At the Bellevue Day Camp it was found impracticable to work out a diet on a scientific basis and the author was not at all convinced of the necessity of planning such a diet, since a wide variation must be made for individual cases. A diet high in fat and proteid

seemed most suitable. Digestive disturbances were less likely to occur if superalimentation was brought about slowly. Constipation should be avoided; at the Day Camp they had found digestive disturbances much less frequent since adopting as a routine measure the administration of a dose of castor oil once each week. Care in regard to forced feeding must be exercised during hot weather and the forced feeding should be avoided altogether on days of extreme heat and humidity. In the pulmonary cases he had used tuberculin only in those cases which did not tend to improve as they should under ordinary remedial measures, and he could not say that he had seen any remarkable results. Usually he had employed old tuberculin, in some cases bouillon filtrate. His initial dose was one-hundred millionth of a gram, and in some cases one-tenth of that amount. Doses were given twice a week, but only to children who could be kept under close observation. For three or four years he had been employing a scale of increase of 25 per cent., which gave ten doses to a bottle, the way tuberculin solutions were usually prepared. In cases of cervical gland tuberculosis he was distinctly enthusiastic over the use of tuberculin. After discussing the different opinions as to the desirability of operating in cases of tuberculous gland involvement, he stated that in all cases of tuberculous adenitis in which surgical measures were resorted to, great care should be exercised if caseation was present to avoid flooding the exposed tissues with tuberculous poison, thus setting up an intense tuberculin reaction which might light up an active focus elsewhere in the body. Pneumothorax should be of value in some cases in children as it was in adults. Among minor remedial measures the hygiene of the mouth, nose, and throat was important. Adenoids should be removed when the disease was quiescent or apparently arrested; hypertrophic tonsils should be removed at a later date as they required longer anesthesia. There was, too, a great tendency to allow children with tuberculosis to return to their normal habits and environments, simply because their general condition was good, though the signs in their chests were still well marked. Dr. Woodruff said he was opposed to the administrative management which permitted tuberculous children in an active or quiescent state to attend school in ordinary classrooms, if they had no tubercle bacilli in their sputum. Such children should be in the fresh air classes, should sleep constantly with the window open, or out of doors, if practicable. They should be discharged on probation, returning once a month for examination; if they continued to improve this period could be gradually lengthened. These children should be carefully guarded against measles, whooping cough, and colds. In speaking of prophylaxis, the author said he was inclined to agree with McCleave, who said that of the strife against tuberculosis in adults much of the effort and money was wasted until it was directed to basic preventive work among children. Prophylactic measures were twofold: (1) to prevent the entrance of infection, and (2) with infection once present, to localize it and to prevent its extension and development, so that a child once infected might be brought up to adolescence with the greatest possible resistance against the disease. With the child in a family where one or more members were infected with tuberculosis, the attempt should be made to prevent too intimate contact with the infected member or members of the family. The need of sanitary furnishings and methods of cleaning in such a home should be emphasized, together with the advisability of sending such children to a different environment or to preventoria at intervals, and educating them in cleanliness and hygiene. In children thus exposed attention to nutrition, to the correction of various physical defects, and to special hygienic care of the nose and throat should be emphasized. They should be seen by their physician at least once in six months, and should have a cutaneous test on their first examination; thereafter they should be tested every four or six months. The care of children who reacted to the tuberculin test was a serious problem in municipal work.

Dr. L. Emmett Holt said he was interested in what Dr. Coit had said regarding the prevention of tuberculosis among cattle. That contact played an important part in the dissemination of the disease was even more true of cattle than of human beings as contact was closer. Dr. Coit had spoken of the cows that were "plugged" with tuberculin by dealers when they were sold. Under existing circumstances it seemed almost impossible to keep tuberculosis out of a herd so long as dairymen continued to introduce new animals into the herd at frequent intervals. In this connection the importance of dairy farms breeding their own cattle for the purpose of replenishing their herds should be emphasized. This was especially important in view of the fact that cows were so often tuberculous though appearing to be in good condition. This was also true of many children with tuberculous lesions; if digestion and assimilation were good, they might steadily gain in weight, but at the same time the disease might be progressive. Dr. Holt asked Dr. Woodruff to tell them what was the relative success obtained in New York with the open air and open window classes.

Dr. Robert Langley Porter of San Francisco, Cal., said that such a discussion as this should not take place without attention being called to the fact there were conditions in which there were non-tuberculous lesions of the lungs in young children. It was interesting in connection with what had been said of bovine tuberculosis to observe that in California it was said that 33 per cent. of the cattle were tuberculous, yet there the cattle were not housed as in the East but lived in the open, and yet infection took place as readily as when the cattle were kept in stables. In spite of the large percentage of infected cattle there was no correspondingly large percentage of infections among children under fourteen years of age. The estimate was that from 7 to 9 per cent. of the tuberculous infection in children was of the bovine type. He felt that the great danger was in the transmission of the infection from one human being to another. There were two points to be emphasized: First, the necessity of minimizing the danger of infection through human contact and especially from carriers so often found in the home. Such carriers were frequently the grandparents, who complained of asthma, winter cold, etc., but who nearly always had tuberculosis. The second point was that they should not assume a child to be tuberculous when such was not the case.

Dr. Charles R. L. Putnam said that for years they had been examining the mesenteric glands to find out how common, relatively, tuberculosis was in the mesenteric lymph-nodes and the lungs. They had found that the lungs might be badly affected and yet the child be free from tuberculous peritonitis, and this apparently showed that the tubercle bacilli could enter and pass through the mesenteric glands without producing permanent lesions of the mesentery or intestine. The infection might be transmitted to the meninges and yet the peritoneum remain unaffected.

Dr. Maurice Fishberg said that he was surprised that in a discussion on bovine tuberculosis in children the problems of immunity were not touched upon. Recent experimental investigations had shown conclusively that reinfection was difficult or even impossible in tuberculosis. Clinically it appeared that the human being was also immune to reinfection with tubercle bacilli. This was evident from the fact no physicians, nurses, or orderlies in hospitals for consumptives had ever been known to be infected with the disease. Similarly marital infection was a negligible factor in the dissemination of phthisis. The reason for this curious phenomenon was that everybody had been infected with tuberculosis before reaching adolescence, immaterial whether phthisis developed or not. Dr. Fishberg pointed out that in children between the ages of three and twelve years of age pulmonary tuberculosis of the types seen in adults was very rare Authorities were in agreement on this subject. Tracheobronchial adenitis was quite common at this period, but this was not phthisis. It had recently been suggested that tuberculosis in children, especially of the glands, was due in a large proportion of cases to the bovine type of tubercle bacilli, and that this bovine infection was not followed by phthisis immediately or in later life. Indeed, some had ventured to assert that bovine infection during the first decennium of life was an important immunizing agent, preventing reinfection with bacilli of the human type. This was a fascinating subject and sufficiently important for investigation. He suggested that Dr. Park, who had facilities and opportunities, should undertake it. With reference to Dr. Bartlett's statement that a large proportion of infections studied at the Babies' Hospital seemed to be due to inhalation, this was not in agreement with the modern view of infection of infants. A large proportion of these infants were partly or altogether brought up on cow's milk, and it might have been bovine infection by ingestion. Even if the bacilli were brought to the child's mouth with the inspired air they might be swallowed. At autopsy it was

exceedingly difficult to say which was the primary lesion. The hypothesis of infection through the inhalation of dried sputum had of late received some severe shocks and it was doubtful if it would hold out against the test of recent research.

Dr. F. H. BARTLETT said, in reference to this question of the inhalation and ingestion origin of tuberculosis that after finding the primary lesion in the lungs and bronchial lymph-nodes in 134 of the 178 cases it would be a far cry to assume that the bacilli passed through the intestines to the bronchi. They had found the primary lesion in the mesenteric lymph-nodes in only seventeen instances, and it seemed fair to attribute these to ingestion. The difficulty lay in proving which was the oldest focus in the body; but assuming that in the 134 cases the primary focus was in the lungs and bronchial lymph-nodes he believed that the bacilli must have gained entrance there by inhalation rather than by ingestion.

Dr. WILLIAM H. PARK said he was surprised at Dr. Fishberg's statement in reference to marital infection with tuberculosis. Several investigators of this subject had found reason to believe that infection did at times take place. It seemed to him that they all must have seen instances where one member of a family after another fell a victim to the disease while caring for one of their number who was suffering from tuberculosis. It might of course be argued that the care and mental depression attendant on such an experience might bring out an early infection that had been dormant. It seemed to him that Dr. Coit was extreme in his requirement that only those having the standing of a professor in veterinary medicine should be permitted to take temperatures; the physician was in the habit of allowing the nurse to take temperatures. Of course the men who took temperatures should be well trained and honest. While infection with the bovine bacilli was possible it seemed equally clear that the great majority of infections in man were transmitted from one human being to another. In cases of fatal bovine infection in which there was a general tuberculosis there was as a rule no way of determining the type of bacilli causing the lesions; the bovine type was exactly like the human in extent and appearance. In cattle the tuberculin test would reveal either type of infection, but as a matter of fact one never found human tuberculosis in cattle unless the cattle were experimentally inoculated with the human tubercle bacilli.

Dr. HENRY L. COIT said that he had it from a veterinary practitioner that the rank and file of veterinarians were not high grade in ability or reliability. He believed that as a proper safeguard to the milk supply they should employ, as he had stated, men of the grade of professor in a veterinary school so that they could make sure of having men of good character and absolute reliability.

Dr. I. OGDEN WOODRUFF, in closing the discussion, said that he thought the relative value of the open-air and open-window classes was a question of climate and equipment and of the amount of money that could be spent on equipment. In New York the open-window classes were conducted in rooms in which the windows were pivoted on two sides of the room and the air was practically the same as the outside air, or just enough heat was supplied to give a temperature of 40° F. He thought this arrangement had certain advantages over the open-air classes because of the excessive humidity and high winds in this climate, and because with the present equipment supplied by the city the children were too cold out of doors. In some private schools the children were entirely out of doors and did well, but they were better protected against cold by warm clothing. Another point to be considered was that the open-air arrangement, while sometimes too cold in winter, was too hot in summer unless a double roof or one so constructed as to afford proper protection against the sun was provided. With the present equipment, Dr. Woodruff said, he greatly preferred the open-window plan.

The Effect of Animal Charcoal in Peptic Digestion.—M. Divella finds that *in vitro* animal charcoal tends to favor the proteolytic action of pepsin. This favoring action occurs only between the limits of 7.35 and 29.4 per cent. solutions of protein. The action does not occur with a quantity of carbon less than 1.47 per cent. of the protein or 0.05 per cent. of the menstruum, or greater than 36.75 per cent. of the protein or 1.25 per cent. of the menstruum.—*Il Policlinico.*

COOPERATION IN THE TREATMENT OF NERVOUS MALADIES.*

BY J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

ASSOCIATE PROFESSOR OF NON-PHARMACEUTIC THERAPEUTICS, MEDICAL DEPARTMENT OF TEMPLE UNIVERSITY.

POSTULATE: Diseases of the nervous system are proverbially complex and difficult to limit or cure. Disappointment is expressed by candid neurologists in the efficacy of remedial measures which appear especially defective in protracted and disabling conditions. This ineffectiveness is less real than apparent; our resources were never before so many or so potent if rightly selected, combined, and supplied. Among the laity an erroneous notion still prevails, viz., that one chosen adviser should be qualified to personally minister to their maladies. This personal intimacy and reliance is precious, but no more capable of radical results here than in other fields of endeavor. The domain of human restitution has long outgrown such primitive methods.

"Nervous diseases," so-called, may be divided into two groups: one, the smaller, includes diseases of the brain, spinal cord, nerves, and directly correlated pathological processes; also another, much larger, viz., diseases of heterogenous origin in which neuropathic and psychopathic phenomena occur as dominant clinical features. Among the latter are manifold disorders in which disease processes are negligible, except as a background for psychoneurotic manifestations. It is this variegated group which forms the most promising field for clinical endeavor since it constitutes the majority, certainly of the more complex and puzzling cases which apply to both neurologists and general practitioners. The proportion of failures here is so great as to constitute a just ground for dissatisfaction with the (apparent) resources of neurology. The problem is to evaluate and determine the effects of these diseases and disorders upon the particular individual; to limit them and to restore him or her to that degree of health of which each is capable. Serious structural affections of the brain and nerves, organopathies, neuropathies, and especially their effects, are notoriously difficult to modify or control; only rarely can they be cured. Few men, even though they be wonders of neuropathological acumen, are capable of becoming experts also in the use of many varied and highly specialized agencies for repair or to successfully qualify as masters in all departments of therapeutics. For them it would seem a large enough demand on time and capacities to diagnose and to efficiently supervise treatment. The domain of nervous disease *per se*, neuropathies and degenerative processes, is enough to keep one man amply employed. They are of gloomy outlook, but advancing resources afford much hope; they need not remain unrelievable. Nervous disorders, dissociation of neurones or personalities, psychopathies in their kaleidoscopic mutabilities are capable also of taxing the resources of any individual. To do them justice, cooperations are needed to yield the combined physical and psychical key.

The whole group of emotive disorders to which the inadequate term "hysteria" is still the popular but misleading designation, constitute a volume in themselves. These are the most numerous, constituting in their milder degrees a majority of most clienteles. (And how helpless are many of those who assume to cure them. Here arise the tragedies in medical experience.) The principles of therapy for this multitude are much alike. There are many common denominators, equivalent principles of action, convertible procedures. They require similar rescue methods and especially reconstructive measures making for both psychic and physical disentanglement, uplift and restitution. Simple as the ingredients may be, special artists are demanded to produce the best fulfillments. Any one man who assumes the responsibility of treating from start to finish all the phases of these metonymic disabilities accepts too large an order. To attempt alone to do one's duty by each and all is bewilderingly perplexing, especially with only unskilled, selfmade or halfmade experts, nurses, clinical assistants. By doing so one invites failure, blunders; may meet well merited blame. Worse than all, many entirely curable persons are thus made to become irremediable derelicts. Among these are often exceptionally valuable citizens brought to a standstill by overstrain and the giving away of weakened tissues, of disorganization of psyche or of substance.

Many conditions encountered among nervous diseases, disorders, and their effects, being generic to other kinds of disability, require similar reconstructive measures. From them all emerge factors stimulating diagnostic skill and rousing therapeutic resourcefulness. These problems range all the way from conditions originating in developmental errors, aggravated by disabling circumstances through acute, subacute, and chronic diseases to degenerative and disintegrative processes. They involve also static or other gross structures, the sense organs, vegetative and reproductive, cardiovascular, renal, and eliminative organs, also the great governing mechanisms, the adrenal system, all in addition to those of the nervous system from which the more graphic features may be derived.

Strange manifestations often occur through vasomotor vagaries, autonomic complexities, plus and minus vagotonies, and sympathectonies. Then

* Read by title at the meeting of the A. M. A., June 19, 1915, Section on Nervous and Mental Diseases.

beyond and behind all these are hyper- and hypotonies of the ductless (endocrinous) glands. All these must be reckoned with before we get down to the levels of structural or other alterations in the brain, spinal cord or nerves and their particularized effects.* To be sure there are innumerable kinds and degrees of neuro- and psychopathic tendencies, all harking back etiologically to familiar origins with bizarre settings. The reason why better results are not achieved are, among others, that interest in neuropathological problems is still exhibited overmuch in scholastic or strictly scientific research and less in the alleviation of distressing or disabling byeffects or residua. Also myriad extravagances in healing methods are exalted by unreliable enthusiasts which excite more suspicion or condemnation than they deserve.

The mind of the scientific investigator is by nature and training skeptical; it tends to esteem dissent as wiser than expectation or hope. His aim is, and should be, to unravel the tangled skein of obscure causes by relentlessly pursuing elusive origins through mazes of complex often inexplicable phenomena and reach the efficient source; to map out structural relationships, associated and interdependent insignia and always to reject phantasmagoria. Such training is the antithesis of hopeful conservation, of optimistic reconstruction.

The *fons et origo* of healing forces, of remedial efficiency, of therapeutic certitude, is hopefulness with a parabolic curve toward optimism. To overcome morbid agencies, psychic or physical, the efficient agency must possess, in addition to reconstructive energetics and restorative capabilities, a large measure of promise which needs to be presented in its most impressive manner. There is needed an atmosphere of confident expectancy. This may well be subjected to special modifications in full accord with tact and diplomatic adaptations to individual makeup, peculiarities, previous history, social plane, mental, moral, and even religious training. The status of physical development demands careful investigation, especially disturbing effects of previous somatic insults, not alone residua of disease, of nutritive defects, but also the circulatory status. Cardiovascular tone, or loss of tone is oftentimes the one factor most demanding restitution.

In this article I allude briefly to certain departments of therapy which seem worthy of special mention, since having helped me, they seem to deserve further elaboration. These are cooperation with the dental surgeon, the hemadenologist, and the reconstructive hygienist. As illustration of the latter, reference will be made to cerebral palsies. Last of all is given a sketch of S. Weir Mitchell as a specialist in cooperation.

Cooperation with the dental surgeon: The significance of certain dental lesions, especially the insidious nonsensory variety, also of impactions, has been shown to be often vital in affecting nerves and brain. Not only are effects obvious and direct through pain causing exhaustion, lowered resistance, and the like; by infections bearing heavily on general or local health, but especially by reflex effects through subconscious or nonsensory peripheral irritation. The subject deserves openminded consideration. Since brought to my attention by the late Henry S. Upson (Professor of Nervous and Mental Disease in the Western Reserve University) it has afforded me the solution of many vexatious problems. If authoritative statement is needed from popular idols let me cite Charles H. Mayo, who remarked at a medical meeting in Chicago recently: "The next great step in medical progress in the line of prevention should be made by dentists. The question is will they make it?" I would assert with emphasis "Will physicians cooperate?"

Anyone will doubtless concede the despotism of the aching tooth, the acute abscess, the humiliating pyorrhea alveolaris, but when the profoundly momentous, subtle, long-continued reflex perturbation induced by steady pressure exerted on a nerve terminal, the slowly accumulating excitation of an impaction, is brought to the foreground of attention, too often it is disallowed or even ridiculed. Only briefest reference can be made here and now to this cardinal domain of cooperative effort. It is true little will be found as yet in medical literature. A surprising mass of testimony is available in dental literature in the form of case reports, *x*-ray details, pathological findings, and the like. All this now needs correlation, association, and should be reduced to sequences and determinations. While the instances wherein this factor has been proven paramount are few, it deserves full consideration in connection with any baffling or seriously retrograding state. Personally I have had many vivid experiences, in which the apparent dental cause being removed, there eventuated extraordinary and unexpected betterments, notably in the psyche. In others the gain was decided; in yet others no decision could be reached as to which factor was dominant. Too often little or no relief was thereby obtained, none the less an operation was fully justified as would be any other *dernier resort*. Evidence as to the etiological bearing of dental irritation is not yet massive, except in the rich findings, case citations, etc., in dental and roentgenological literature, which the Upson Foundation will now afford means for collecting and digesting. As a clinical resource it promises much in the face of otherwise hopeless neuro- or psychogenic miseries. It is my opinion, affirmed with increasing confidence, that no neurologist does his full duty by certain kinds of cases till an *x*-ray plate is made of all the teeth wherever suspicion is aroused as to possibilities of dental irritation being a causal factor in disorganization of psyche or substance. Psychoses due to irritation by impactions are said by Upson to differ in no notable particular from those due to abscess. Critical study of suppurative processes shows that not only the quantity of the absorbed pus, but likewise its situation as an irritant as well as its neuronic associations is a determining factor in somatic or psychic integrity. An abscess is commonly pacific. It may cease to be so by reason of subsiding degrees of suffering, and by compensations. The pain grows less, or awareness is obtunded, till it sinks below the threshold of consciousness, yet continues to exert irritation, inducing deeply acting, farreaching effects.

Briefly, the short route recommendation is to

*Smith Ely Jelliffe said in his presidential address: "It had seemed feasible to regard the nervous system, speaking broadly as operating at three levels: through the course of ages these had been built up, not sharply delimited, but gradually and imperceptibly merging the one into the other. These familiar levels he would speak of as the vegetative, the sensorimotor, and the psychical levels respectively, and would use the terms, vegetative neurology, sensorimotor neurology, and psychical neurology, not as indicating three different kinds of neurology, but rather working at different functional levels, no one of which can be neglected.

remove the tooth causing any marked impaction or any recognizable evidence of alveolar abscess. To be sure few dental surgeons will or can be induced to accept this view, they being trained to save the tooth whenever possible. There are appropriate dental relief procedures, radical in character which surgeons are now capable of supplying if they will. The results of pus removal must emphatically be complete and thorough, or the neurogenic abnormality will persist, and valuable time and remediabilities will be lost. Insanities may and do result. A life may be blighted to save a tooth as I well know. Intances could be cited when indomitable persistence over a period of time was required to achieve the emancipation.

Hemadenology as an adjunct to neurology and psychiatry: The new and comprehensive specialty, hemadenology, proposed by Sajous, the science of the blood glands, has so expanded as to afford the essential explanation of many obscure psysiological processes, anomalies, and diseases. By its aid also it is possible to elucidate the complex effects of disordered states, grouped clinically among diseases of the nerves, displaying characteristic phenomena neurotic and psychic, which arise in the deeper levels of growth forces and manifest secondary effects on brain or nerve structures. Since this clinical domain has been shown to offer such efficient means of solving hitherto insoluble problems, neurologists do well to familiarize themselves with the essential principles and apply them in daily work. To do so presents difficulties for those whose time and strength is already fully occupied along familiar and otherwise expanding lines. Hence for the present, best results can only come by the cooperation of that small group giving special attention to hemadenologic investigations.*

Correlationships these studies exert on neurologic and psychopathologic problems are, among others, these: The field of the internal secretions may now be regarded as all-embracing. Whether the thyroid, the adrenals, the pituitary or any other of the ductless glands can be regarded as definitely involved, in a given instance, phenomena often appear only comprehensible by studying them from this standpoint of origin or departure. For example, on general nutrition, as in obesity of hypothyroidism, hypopituitarism, or hyperadrenalism; also on skeletal structures, vascular system and musculature as in acromegaly or gigantism, both being of pituitary origin. Gout, atheroma, glycosuria, and many closely associated disorders which form the basis of neurogenic disorders are now known to be intimately related to disturbances in the adrenal system. So also of vulnerability to infections, and, in particular, the more obdurate effects and complications of infections are traceable to acute diseases of these glands.

This brings us to the whole subject of immunology. Developmental anomalies are to be similarly explained. Notably the vast army of backward minded, the psychic aberrancies, eccentricities and defects. Anomalies in some instances which exhibit stigmata point directly to impairment through heredity or environmental influences to acquired lesions of the ductless glands. So in infantilism, characterized by persistence of childish characteristics, but with it dwarfism or gross mental defect; also obesity with femininism; also certain grave sociological problems, the evildoer, the fool, the delinquent, the petty criminal. Some of these find their origin in loss of balance in the ductless glandular activities. These are often to be benefited, moreover, sometimes cured, by eliciting the associations in, equipoise of the blood glands, by production of hormones, insuring normal metabolism in all structures, particularly those of the central nervous system. Insanity, too, in some of its phases is similarly explainable and remediable, notably dementia precox, constituting as it does about one-fourth of the inmates of all asylums, with treble that number at large. This deplorable disease has been differentiated into certain forms based upon aberrancies in the ductless glands by Ludlum and Corson White, and they have succeeded in ameliorating some varieties by organotherapy.†

Psychasthenic and neurasthenic phenomena are oftentimes traceable to the same developmental and metabolic defects. This is true, too, of certain acquired phychoses and neuroses, post febrile and post operative. "In psychopathic affections the disturbance consists in the formation of nonadaptive associations of central neuron-systems with receptors which normally do not have as their terminal response the particular motor and glandular reactions." (Boris Sidis.) Not to be forgotten, too, are the baffling borderline conditions where individuals, apparently in full health, exhibit inexplicable peculiarities, "idiosyncrasies," susceptibilities, emotionalisms, imbalances in self-control, in judgment and impulsions or even in anomalies of structure, as in features. Among these are the larval or mild forms of hypothyroidism, of dyspituitarism or of hypoadrenalism. Few problems are more difficult of solution than those dependent on anomalies of the thymus, a subject as yet obscure but becoming revealed to the specialist in hemadenology. Finally to be mentioned are the trouble makers, the reproductive organs, sex energies, impulsions, and all that they imply. Clinically, both in direction and correction they belong in part to the domain of the ductless glands.

Reconstructive Personal Hygiene: Including regulation of items of conduct particularized for definite needs, whereby latent powers can be rendered available, inherent energetics brought to the front to meet exigencies of the individual in overcoming difficulties, in restitution of function, chiefly along the sensorimotor levels.‡

Postulate: Enormous potentialities reside in training voluntary movements with the purpose of readjusting static and also other structures (Kinesitherapy), hence making for mechanical easements of local pressures interfering with function, also expediting local and general nutrition, hence for restoration of local disabilities. Note the significance of errors of posture, the economic advantage of recovering impaired degrees of attitude of

*For example: Exceptional opportunities have been mine to learn something of the subject by a close personal association with the masterful contributor to this fertile field of endeavor, Dr. Sajous, who has taken pains to teach me, supplying first hand information of his many discoveries, inferences, and conclusions. With perhaps no greater defects of intelligent apperception than the average clinician, I find it necessary to frankly refer most problems to his acumen and experience. I have thus been able to make some efficient clinical deductions and apply remedies with unexpected success.

†Ludlum, S. D. N., and Corson White, E. P.: "The Thymus and the Pituitary in Dementia Precox," *Amer. Jour. Insanity*, April, 1915.

‡A mere catalog of headings only is offered. Most of them have been or are being elaborated by the author.

mobility, pliancy, flexibility, elasticity, *e.g.* in the thorax, the spinal column and accessory structures; also of tone in supporting structures, abdominal walls, compensatory action of diaphragm, and the like. By such measures stagnation is relieved in viscera, especially in the lower abdominal quadrants, activation of circulation, lymph propulsion, venous blood, nerve impulses, also reaction times and other factors of thigmotropic readjustment bearing on biochemical and also psychomotor and sensorimotor competence. Note also the corollary (akinesitherapy) rest treatment, abundantly elaborated from Hilton to Weir Mitchell, Playfair, and modern phthisiotherapists. Note also passive movements or chiefly passive and moderately cooperative movements which demand the personal attention of the physician or at least his critical supervision and particularized direction. This measure has not begun to receive the scientific scrutiny it deserves, as can only be known by one who has labored faithfully in the field and compared effects. Among the conditions in which judicious passive, stretching, torsion, or hand applied movements are capable of large and increasingly beneficent consequences are: resultants of poliomyelitis, cerebral palsies, tabes, some paraplegias, effects of some cord-lesions, some stages of neuritis and some of paralysis of special nerves, of most neuralgias (notably when fibromyositis is present), in tics, spasms, most valuable in paralysis agitans (see three papers by the author). Occasionally in acroparesthesia and in paralysis of plumbism. Also in some of the disabling and distressful phenomena of premature ageing, of degenerative processes, in arthropathies, in cardiovascular changes, in impairment of sensorimotor integrity, notably of the ear, eye, and nasopharynx; disabilities of the neuromuscular mechanisms, and particularly of the gastrointestinal tract, flatulence and minor shocks, intestinal stasis, adhesions, kinks, angulations, also enteroptosis, nephroptosis, local tonic spasms or relaxations, of abdominal parietes.

The whole splanchnic blood vessel system which, when markedly depressed or stagnated contributes largely to the effects, if not the causes of, neurasthenic, psychasthenic phenomena are alleviated by hand pressure and lifting of the subdermal structures, training of the abdominal parietes, diaphragm, thorax, and correlated semi-voluntary structures. Also "the great skin heart," the surface blood vessels, so often assumed to be normal in a given case of nervous disease yet in reality disordered, are vastly benefited by subdermal traction, the full equivalent of "passive hyperemia," and often constitutes the key to progress.*

As an example of kinesitherapy let me cite: Cooperation in treating the effects of cerebral palsies. Factors in cerebral palsies, causes and conditions to be reckoned with are: (1) Primary damage to motor centers and areas of brain, and (2) to subsidiary centers; the problem and phenomena vary with age and condition of life, stage of evolution in development and in growth forces, producing alterations in structures upon which primary and secondary effects are wrought. (3) Limitation of motor capacity and coordinate efficiency due to: (a) original damage, partial or complete; (b) depreciation in motor impulse and in encouragement to energizing from, or discouragement to, effort, hence formation of habits of inactivity, indifference, cessation of effort, hence increasing incapacity; (c) local spasms, contractures, rigidities, impairments of tissue elasticity, mobility and pliancy; (d) concurrent myopathic disabilities, connective tissue and aponeurotic changes, fibromyositis.

Motivation becomes impaired all along the line from primary impulse to precision in execution. Whether there exists an unusual weakness or fatigability may be in doubt; certainly impulse to energize is diminished probably because of long disuse and discouragement. Hence the motor cells involved in the brain need awakening and stimulating by conscious motor impulsions. The question then presents: how far can primary effects be overcome? (1) By mechanical and other stimulation, by volition, domination by one's self or by extraneous domination, and (2) also by passive effects wrought by electricity. (Many cases will be found to have received ample electrical treatment from the first.) (3) By passive movements, stretching, torsion, and specifically guided motor training.

The late S. Weir Mitchell was a marvel of proficiency in curing patients. Those associated with him professionally, usually endeavor to appropriate and apply his methods. To those of his assistants having experience with other neurological clinicians illuminating contrasts are afforded. In my opinion the chief instrumentality of his amazing successes was his prompt and cordial cooperation with experts in correlated lines, and himself not attempting to do it all. The distinguishing characteristic of Dr. Weir Mitchell was his radiant energy and his clear-sighted recognition of the value of joint action. He so stimulated the zeal of his adjutants as to get the best out of them not only in diagnosis but in treatment. Thus an efficient coalition was constantly at work. He uniformly said and did the judicious thing to create and maintain team work. In leadership he was wisdom personified in plan, in strategy, in shifting the point of approach, in creating useful surprises, in persistent effort, thus achieving the most economic and permanent results.

The patient was taught and insensibly assumed his or her share in the campaign. In my long years of association it always seemed his tactful management surpassed in curative efficacy all other measures. His remedies were generally of the simplest, most rational, well chosen, and above all, consistently applied and over sufficient periods of time. He uniformly depended upon the united efforts of all collaborators, conferring on them a measure of responsibility by deferring to their judgment, making them sharers in the credit for successful endeavor. Thus not only were sidelights supplied on obscure problems, but no force was lost in the transmission and concentration of beneficent energetics. He conferred an element of partnership on nurses, masseurs, clinical and laboratory assistants of various degrees; on specialists whom he freely consulted, highly esteeming the findings of experts in the sense organs, in surgery, gynecology, orthopedics, electricity, massage, remedial exercises to an extent then unheard of, and even now unsurpassed. As newer sources of evidence came to the front he eagerly welcomed them. He was among the very first to realize the significance of

*I have repeatedly been able to afford unexpected relief to a host of obstinate disorders by giving adequate attention to the skin, loosening the adherent subdermal structures, rich in nerve, blood and lymph supply, which thus can be freed from stagnation, and the whole organism benefited. See paper by author, "Cardiovascular Renal Regulation," Internat. Clinic, Vol. 1-24, Series 1914.

"the pathology of the living" as now furnished by modern surgeons after removing concealing tissues, and then seeing, touching, and readjusting the parts below.

Thus was assembled a complete group of precise observations, reliable findings, and candid opinions. Each ally was put upon his mettle by the flattering openmindedness of the "chief." Mature judgments were thereby formed consonant with the facts at issue. Doubtless most master clinicians now aim to do most of these things. Then we constituted a unique confraternity. Every one of us who enjoyed his confidence strove to surpass ourselves in winning his approval and in contributing to desired results. There were times when so large and varied was the company of sufferers seeking his help that omissions must have occurred, even blunders, had he not harmonized our best efforts. So devoted were we to his personal interests that our vigilance and loyalty filled in many gaps and added materially to the success of the economic régime.

Dr. Mitchell was pre-eminent in penetration, in a knowledge of mankind on all social planes and conditions of life, in subtle appreciation of niceties of difference in mental and moral make-up, in those factors which contribute to peculiarities in belief, fears, hopes, ambitions, and in domestic tangles. Above all, he had vision, instinctive awareness of complexes and of the essential needs of any invalided human being. He was well versed not only in physical but also in mental and moral pathology. He also became an adept in unusual remedial agencies which many neurologists even now regard as beneath their attention or confidence. For example, he himself had learned to apply massage, various manipulative measures, and hence was quick to determine the capabilities of masseurs and judge the quality of their work. He could and did teach precisely what he wished done for a particular condition.

Many neurologists declare there is little or no real value in massage. Thus they either unfairly belittle it or are incapable of appreciating its efficiency, or directing its use. Of course, no efficient results can follow such half-hearted measures. He was also a master in the art of using heat and cold, balneotherapy, wet packs, drip sheets and the like, showing shrewdness and originality in modifying and adapting all such physicodynamic measures to meet varying conditions. So also of a host of other remedial agencies which are too often either omitted for lack of knowledge of the principles or unfamiliarity with or unaware of the nature of effects to be expected. To nurses he supplied a new and liberal course of instruction in their art; a special group of experts were thus evolved. So likewise of his clinical assistants. We entered a novel and fascinating school of resourcefulness and art. Upon us devolved a new and varied line of duties scarcely hinted at in the schools.

We were kept busy in an ever-improving yet simplified system of reconstructive hygienic measures the purpose of which was to raise the vital index and the psyche of an individual to a higher plane than it had ever reached before; to render latent powers available; not alone to remove urgent disabilities. In short, we were grounded in the fundamental principle of therapy, viz.: to render the best kinds and qualities of joint service in our power to a sick human being.

1504 Pine Street.

A RATIONAL METHOD OF TREATING LOBAR PNEUMONIA.

WITH A REPORT OF ONE HUNDRED AND THIRTY-THREE CONSECUTIVE HOSPITAL CASES IN WHICH IT WAS USED

By EDWARD E. CORNWALL, M.D.,

BROOKLYN, N. Y.

ATTENDING PHYSICIAN TO THE WILLIAMSBURGH AND NORWEGIAN HOSPITALS; CONSULTING PHYSICIAN TO THE BETHANY DEACONESSES HOSPITAL.

In papers read before the Kings County Medical Society on April 15, 1913,* and the Greater New York Medical Association on March 16, 1914,† the writer reported consecutive series of twenty-nine and fifty-four hospital cases, respectively, of lobar pneumonia treated by the method which is described in this paper. That series has now, May 1, 1915, reached 133 cases, and the results observed seem of sufficient interest to warrant a further report.

Distinctive Features of the Method of Treatment.—1. The ground is cleared by a recognition of the following facts: First, that attempts hitherto made along the line of specific chemotherapy in lobar pneumonia have invariably proved failures, as they have in all other diseases of strictly bacterial origin, and that the probability of the eventual discovery of a successful drug specific for this disease is too slight to encourage further experimentation along this line. Second, that while a serum or vaccine treatment for lobar pneumonia may be hoped for and looked for, no effective treatment of this character which is practically available has yet appeared. Third, that Nature has devised a method of treating this disease which by itself can cure a large proportion of cases, and that any method devised by the physician, in order to be rational, must be subordinate to Nature's method.

2. A particular, specified diet is given, which is modified in definite ways to meet special indications. This diet is limited in quantities of protein and fuel to somewhat less than the minimum health rations, it is fluid, it is easy of digestion, it supplies salts needed by the body, and it is non-putrefactive.

3. Evacuations of the bowels are not artificially induced as a rule, although in exceptional cases laxatives of a mild character are given.

4. Agents to stimulate the heart are given according to a definite plan, which is flexible in prescribed ways to meet particular indications.

5. The treatment of symptoms is exceedingly conservative; care is taken while attempting to relieve symptoms, to avoid using agents which might increase in other directions the difficulties which beset the patient; and many of the therapeutic procedures for the alleviation or modification of symptoms which are commonly employed are not used.

How the Diet Is Given.—The diet is given according to three regular prescriptions, which are subject to definite modifications to suit particular conditions. The first prescription is for the active period of the disease, and the second and third for the convalescent period.

Prescription 1.—To be taken during the febrile period and for two or three days after defervescence.

8 A. M.—Give 7.5 ounces of a two to one mixture

*E. E. Cornwall: "Observations and Suggestions Regarding Lobar Pneumonia," Medical Record, Aug. 2, 1913.

†E. E. Cornwall: "Lobar Pneumonia, Fifty-four Cases Treated by a Special Method," *N. Y. Medical Journal*, May 30, 1914.

of milk and barley water to which has been added 5 grains of sodium chloride.

8:30 A. M.—10 grains of calcium chloride dissolved in 5 ounces of water.

10 A. M.—7.5 ounces of the milk and barley water mixture.

11 A. M.—7.5 ounces of orangeade made with the strained juice of one orange, one ounce of milk sugar, and water.

12 M.—7.5 ounces of the milk and barley water mixture.

12:30 P. M.—10 grains of calcium chloride as before.

2 P. M.—7.5 ounces of the milk and barley water mixture.

3 P. M.—7.5 ounces of the orangeade.

4 P. M.—7.5 ounces of the milk and barley water mixture.

4:30 P. M.—10 grains of calcium chloride as before.

6 P. M.—7.5 ounces of the milk and barley water mixture.

8 P. M.—7.5 ounces of the milk and barley water mixture.

8:30 P. M.—10 grains of calcium chloride as before.

10 P. M.—7.5 ounces of the orangeade.

Administer everything through a tube, without raising the patient's head.

Modifications of Prescription 1.—A. Substitute for any or all of the milk and barley water feedings any of the following: Peptonized milk diluted with one-third barley water or plain water, buttermilk, lactacidized milk, or one of the predigested cereal foods dissolved in water.

B. Substitute in place of all the milk and barley water feedings any of the following: barley water alone, rice water alone, or water alone.

C. The same as modification B, with omission of the orangeade.

D. The same as prescription 1 or any of its modifications with omission of the calcium chloride.

Prescription 2.—To be taken on the third day after defervescence in uncomplicated cases. The same as prescription 1 or prescription 1-A with substitution of 6 ounces of moist cooked cereal and 3 ounces of milk, an equal quantity of boiled rice and milk, and two slices of milk toast, for three of the milk and barley water feedings respectively, with omission of the calcium chloride.

Prescription 3.—To be taken on the sixth day after defervescence in uncomplicated cases. Breakfast: 6 ounces of moist cooked cereal with butter, cream, or milk; two slices of toast and butter with one poached egg or two ounces of cream cheese or pot cheese; an orange, grapefruit, baked apple, or peach; a glass of any of the above mentioned milk preparations or of milk diluted with one-half weak tea. 10:30 A. M.—A glass of any of the above mentioned milk preparations or predigested cereal food preparations.

Dinner: 7 ounces of milk soup, viz., cream of corn, celery, potato, carrot, oyster plant, spinach, or green pea, or a glass of any of the above mentioned milk preparations; two slices of old bread or toast and butter; any of the following vegetables: potato, carrot, spinach, string beans, celery, oyster plant, or green peas; lettuce or raw cabbage with olive oil and lemon juice; 2 ounces of cream cheese or pot cheese or one and a half ounces of American or Edam cheese; 6 ounces of maccaroni, spaghetti, or boiled rice with butter, milk, or grated cheese; fruit as at breakfast. 4 P. M.—A glass of any of the above mentioned milk preparations.

Supper: A bowl of bread or rice and milk, or any of the above mentioned cereal preparations; a baked apple.

Give water as desired.

Prescription 1 supplies about 38 grams of protein and fuel of the value of about 1,200 calories; 35 grains of sodium chloride, and 40 grains of calcium chloride in addition to the salts in the articles of food given; and 95 ounces of water. It serves as a standard diet for the febrile period, and a maximum diet except as regards water, which may be given freely as desired. In all the prescriptions the addition of cane sugar or spices is forbidden.

How the Bowels Are Managed.—The dangers which threaten from the bowels in lobar pneumonia are chiefly those due to the absorption of intestinal toxins, to abdominal distention, and to reflex nervous disturbances. Of the toxemias which come from the intestines the most important are those produced by the activity of the bacteria of putrefaction and other more or less habitual residents of the gut, and the specific toxemia due to the absorption of the endogenous poisons of the swallowed pneumococci which multiplied and died in the alimentary canal. These toxemias can be greatly lessened in amount by avoiding the ingestion of culture media favorable to the growth of the bacteria which produce them, and by including in the diet articles which encourage lactic acid fermentation; and the dietetic regulations above described, which constitute an integral part of this method of treatment, are arranged with close regard to that point. This plan of diet also constitutes a safeguard against abdominal distention. It also lessens to a considerable extent the third danger, viz., that from disturbing nervous reflexes of abdominal origin; but that danger requires a further safeguard. Evacuations of the bowels, particularly those which are artificially induced, seem capable of exciting nervous reflexes which can seriously disturb the heart when that organ is on the verge of exhaustion. In lobar pneumonia the heart is often in such an unstable condition that a very slight disturbance of it is sufficient to determine a fatal issue. Here is found an indication to avoid unnecessary catharsis, to say nothing of the violent purgation which is so commonly practised as a routine procedure in the treatment of this disease. We are fortunately able to withhold cathartics in this disease during its active period when the above described diet is given, because that diet leaves very little residue and discourages injurious bacterial activity.

In the management of the bowels according to this method of treatment the following rules are observed: If the bowels have moved satisfactorily within twenty-four hours before coming under observation no attempt to move them artificially is made unless some special indication appears. If more than twenty-four hours have elapsed since the last movement and the disease is in an early stage and the heart is in good condition a simple or soapsuds enema is given, or a dose of castor oil, or other mild vegetable cathartic (never a saline). If the disease is in a later stage, that is, on or after the fourth day, or if there are signs of heart strain, no evacuation is induced, even if a longer period than twenty-four hours has elapsed since the last movement, except in some, not all, cases with tympanites, which may call for enemas. On the second

day after defervescence, if the bowels do not move spontaneously, an enema is usually given, and thereafter laxatives are given as required.

How the Heart Is Stimulated.—In young or middle-aged adults with originally healthy hearts stimulation is usually delayed until signs of heart strain appear, which is usually not later than the fourth day. The first stimulant given is strychnine sulphate, in doses of one-sixtieth of a grain three times a day or every four hours. If the pulse becomes unduly rapid or the right ventricle shows signs of dilatation, tincture of strophanthus is also given, in doses of one and a half minims every four hours. If the signs of cardiac strain become pronounced, the dose of strophanthus is increased to two and a half minims and the dose of strychnine to one-thirtieth of a grain, and perhaps citrate of caffeine in two grain doses every four hours is added. More than this amount of stimulation is seldom required in patients treated according to this method, but if it should seem to be required digitalin in doses of one-hundredth to one-fiftieth of a grain is given hypodermically every four hours, and perhaps spirits of ammonia in doses of one-half a dram every one or two hours is added. When more stimulation than that afforded by the strychnine, strophanthus, and caffeine is required the prognosis is usually bad. In the very small proportion of cases which show a gastric or intestinal idiosyncrasy in respect to strophanthus that drug should be omitted and caffeine substituted as the second stimulant. In the aged, in alcoholics, and in patients with pre-existing heart disease stimulation is usually required from the beginning. In the aged and in alcoholics whiskey or brandy is usually given in small doses throughout the disease. In infants and young children heart stimulants are almost never given, even though the pulse may be very rapid.

How Special Symptoms Are Treated.—In the treatment of symptoms according to this method the general rule is to do as little as possible. Some symptoms, however, are entitled to alleviation by medical art and should receive it.

When pain, cough, restlessness, or insomnia harrass the patient and deprive him of necessary sleep, they are relieved by the application of hot poultices to the chest and perhaps by the administration of morphine or codeine in small doses, but the opiates are given only in the early stages of the disease, for they are absolutely contraindicated in the later stages and in any stage if there is much respiratory embarrassment. Restlessness at the time of the crisis is usually considered an indication for more heart stimulation.

Diarrhea is treated by restriction of the diet to barley water. Vomiting is treated by stopping all food for a while, and perhaps, if in an early stage of the disease, by small doses of morphine.

Tympanites, which is of rare occurrence in cases treated according to this method, calls for reduction of the diet to barley water and orange juice alone, to barley water alone, or to water alone, and if it is severe, it may call for a simple enema or one of soapsuds or fel bovis, and perhaps the introduction of the rectal tube.

Some Things Which Are Not Done.—An important feature of this method of treatment is the negative feature, which consists in not doing certain things which are very generally done, and which even have the sanction of good authority. Among the avoided procedures are the following:

Calomel and magnesium sulphate are never given in this disease, nor any saline or drastic cathartic, nor any cathartic at all except in certain particular conditions. Letting the bowels alone after having safeguarded the patient by dietetic regulation from the dangers that might come to him from retention of the bowel contents, has already been mentioned as a special feature of this method of treatment, but the routine use of calomel and magnesium sulphate and of excessive purgation in the treatment of this disease is so widespread, that the writer refers to the subject again to emphasize its importance.

Antipyretic drugs or procedures are not used. There seems to be good reason to believe that fever in pneumonia is a conservative process on the part of Nature, and exists for a constructive purpose, and it is a matter of general observation that the cases with a considerable elevation of temperature are apt to do better than those with but little fever.

No drug duretics are used. Water, however, is given in reasonable amount.

Expectorant drugs are not used. The futility or worse of giving expectorants in pneumonia would seem to be obvious.

Digitalis is never given by mouth, although it is, rarely, allowed by hypodermic injection.

While fresh air is insisted on, cold drafts are not permitted to blow on the patient when his temperature is normal or nearly so.

Drugs for an alleged intestinal antiseptic effect are never used. The intestinal flora are controlled more safely and more effectively, it is believed, by regulation of the diet.

The various drugs which have been recommended for an alleged specific or quasi specific effect, such as creosote carbonate, salicylic acid, quinine, urea and quinine hydrochloride, urotropin and camphor, are ignored.

Statistical Report.—This series of 133 hospital cases is a continuous one, and includes all of the cases diagnosticated as primary lobar pneumonia (of which a few may have complicated the grip) which were treated by the writer in the Williamsburgh and Norwegian Hospitals between January 1, 1913, and May 1, 1915; 102 occurring in the Norwegian Hospital and 31 in the Williamsburgh Hospital. The series being continuous and not selected, includes cases which were poor subjects for treatment, cases which came into the hospital late in the disease, cases which had been neglected or even maltreated, and cases which were moribund when first seen.

Ages.—Twenty-one were under 5 years, eleven between 5 and 15, thirty-four between 15 and 25, twenty-eight between 25 and 35, nineteen between 35 and 45, fifteen between 45 and 60, and five over 60.

Lobes Involved.—The right lower lobe only was involved in 49 cases, the left lower lobe only in 47 cases, the right upper lobe only in 11 cases, the right middle lobe only in 6 cases, the left upper lobe only in 4 cases, both lower lobes in 6 cases, both left lobes in 6 cases, the right lower and right middle lobe in 3 cases, and the right upper and right middle lobe in one case.

Maximum Temperatures.—In nine cases the temperature rose to 106° F. or higher, in twenty-three cases to between 105° F. and 106° F., in forty-five cases to between 104° F. and 105° F., in thirty-two cases to between 103° F. and 104° F., in thirteen cases to between 102° F. and 103°

F., in nine cases to between 101° F. and 102° F., and in two cases it did not rise above 101° F.

Maximum pulse rates.—In three cases the pulse rate rose to 180 or more, in four cases to between 170 and 180, in thirteen cases to between 160 and 170, in eight cases to between 150 and 160, in eighteen cases to between 140 and 150, in thirty cases to between 130 and 140, in twenty-six cases to between 120 and 130, in sixteen cases to between 110 and 120, and in fifteen cases it did not rise above 110.

Maximum Respiration Rates.—In ten cases the respiration rate rose to 70 or more, in seventeen cases to between 60 and 70, in twenty-three cases to between 50 and 60, in forty-nine cases to between 40 and 50, in twenty-nine to between 30 and 40, and in five cases it did not rise above 30.

Minimum Blood Pressures.—In sixty-four of the cases which recovered, examinations of the blood pressure were made one or more times. In one of these sixty-four observed cases the systolic blood pressure was found at 70 mm. Hg., in one case at 85, in five cases at 90, in seven cases at 95, in twelve cases at 100, in nine cases at between 100 and 110, in seventeen cases at between 110 and 120, in five cases at between 120 and 130, and in seven cases at over 130. In forty-nine of these cases the systolic blood pressure fell below the pulse rate, yet all recovered. These observations throw doubt on Gibson's assertion that when the systolic blood pressure, in millimeters of mercury, falls below the pulse rate, the prognosis is bad.

Leucocytosis.—In thirty-five consecutive cases of this series, which were treated in the Norwegian Hospital during the first quarter of the present year, 1915, leucocyte counts were made, and in all the cases except two a leucocytosis of over 10,000 was found. The average count was 18,000.

Defervescence.—Defervescence took place by crisis in sixty-four cases and by lysis in thirty-nine cases. There was delayed resolution in eleven cases. Four cases came under observation at the time of defervescence without a previous history being obtained. Four cases were followed by empyema before defervescence. Eleven cases died before defervesence. The average duration of the fever in the sixty-four cases which defervesced by crisis was 7.8 days, and in the thirty-nine which defervesced by lysis, 8.8 days.

Complications.—Pleurisy with effusion was noted in one case, pericarditis with effusion in one case, acute endocarditis in one case, empyema in five cases, delirium tremens in three cases, abscess of the lung in one case, and delayed resolution in eleven cases and abscess of the lung in one case.

Mortality.—Fourteen of this series of one hundred and thirty-three cases died, giving a mortality of 10.5 per cent.

The Fatal Cases.—Case I.—Boy, 11; died the day after defervescence, of what cause was not ascertained.

Case II.—Man, 49; heavy drinker; entered the hospital in the fifth day of the disease with a badly dilated right ventricle and a systolic blood pressure which remained mostly between 80 and 90 until shortly before his death, which took place six days after admission, when it rose suddenly to 120, probably from asphyxiation. In this case influenza apparently preceded the onset of the pneumonia.

Case III.—Woman, 49; entered the hospital in the fourth day of the disease with two lobes involved, a badly dilated right heart, a blood pressure of 90 systolic and 70 diastolic, a pulse rate of 160, and extensive pulmonary edema; she died in thirty-six hours.

Case IV.—Man, 58; walked around for three days after his initial chill, and entered the hospital with a badly dilated right ventricle, extensive pulmonary edema, and a blood pressure of 70 systolic and 50 diastolic; he died in twenty-one hours.

Case V.—Man, 19; was removed to the hospital from a ship in the harbor in poor condition.

Case VI.—Man, 28; had delirium tremens.

Case VII.—Man, 50.

Case VIII.—Man, 41; walked into the hospital in the fifth day of the disease; had delirium tremens.

Case IX.—Woman, 38; entered the hospital in the sixth day of the disease with a failing heart and extensive pulmonary edema; she died in five hours. This patient was reported to have taken a large dose of magnesium sulphate the day before she entered the hospital.

Case X.—Man, 44; walked into the hospital in the fifth day of the disease; had delirium tremens.

Case XI.—Man, 57; died shortly after the crisis. At the time of the crisis he was given, without the writer's knowledge or approval, one sixth of a grain of morphine and an enema.

Case XII.—Man, 51; came into the hospital in a moribund condition, and died on the second day; had been a vagrant, sleeping in open sheds.

Case XIII.—Man, 18; died on the twenty-ninth day after admission, having had a persistent consolidation of the lung and a continuous fever. A clinical diagnosis of tubercular pneumonia was made in this case, but it lacked confirmation by a pathological examination.

Case XIV.—Woman, 29; entered the hospital in the ninth day of the disease; had delayed resolution; evidences of abscess of the lung appeared, and she died on the forty-seventh day after admission. The discharge from the lungs showed streptococci and staphylococci.

Besides the fourteen fatal cases above mentioned, there were two in this series which died after apparent recovery from the pneumonia and from other causes. One of them underwent an operation for empyema and died of general sepsis after thirty-three days, and the other, after defervescing regularly and remaining without fever for more than a week, suddenly developed symptoms of cerebral congestion and died twenty-eight days after admission.

Suggestive Observations.—From the observations made on this series of cases of lobar pneumonia treated by the method described, no positive conclusions are drawn, because the number of cases is comparatively small and because the disease is one which varies much in its clinical manifestations and in the type and virulency of its pathogenic microorganism. Some of these, however, were suggestive, notably the following:

1. Toxemic symptoms were rare.

2. Tympanites was almost unknown except in patients who entered the hospital with it.

3. Constipation was well borne. Some of the patients went without a movement of the bowels for five, six, seven, and even eight days, and showed no unfavorable symptoms on that account. In many of the cases the constipation was spontaneously relieved.

4. Thirty-two of the cases showed a temperature of 105° F., or higher, but only four of the deaths occurred among that thirty-two.

5. The systolic blood pressure fell below the pulse rate in seventy-five per cent. of the cases which recovered and in which blood pressure examinations were made.

6. The pulse rate in forty-six of the cases, more than one-third, reached 140 or more, and in seventy-six it reached 130 or more; and in many of these cases the rapid pulse persisted for a considerable time, and the myocardial endurance seemed, in general, to be greater than that observed in former experiences with pneumonia treated by other methods.

THE RESPONSIBILITY OF THE STATE IN THE TUBERCULOSIS MOVEMENT.*

By EDWARD O. OTIS, M.D.,

BOSTON.

I THINK we are all agreed that the efficient prevention and control of tuberculosis in the State is beyond the power and means of private instrumentality. In one section of the State, as in a large city, for example, a complete and intensive campaign against the disease may be instituted, while in another section but little may be done, or only spasmodically done if dependent upon private and local action. To combat the disease most successfully and economically throughout the State there should be a general, comprehensive, uniform plan of procedure directed by one central administrative body, whether it be the State Health Department or a board of trustees appointed for the special purpose.

There are five principal lines of attack in the tuberculosis campaign which I believe the State can best direct, aided more or less by private endeavor in local communities.

First. Education, which the State Health Departments have been doing to a greater or less degree for several years; by literature, traveling tuberculosis exhibitions, lectures, etc. Private tuberculosis associations can render much assistance in this direction; indeed, it seems to me that the educational propaganda is one of the main functions of such associations. In the State of Massachusetts, tuberculosis is required by law to be taught in all the secondary schools.

Second. Compulsory notification by physicians and householders, and the free examination of sputum in the State laboratory. So far as I know, nearly if not quite all the States now require the one and do the other, although many of the large cities in the country were in advance of the State in the requirement and the service.

Third. Tuberculosis dispensaries, which are either established directly by the State, as in Pennsylvania, or by the various communities under State supervision. In the State of Massachusetts each city or town of 10,000 inhabitants or over is required by law to maintain such a dispensary which must be approved by the Health Department of the State.

Fourth. State sanatoria for curable cases. In Massachusetts there are four such sanatoria, one of 350 beds and three of 150 beds each; and in one there is a children's department. Each patient is required to pay $4 a week, or, if he is unable to do this, the State collects the amount from the city or town from which the patient comes.

Fifth. Consumptive hospitals for advanced indigent cases. Such hospitals, in my opinion, should be local so that the patient may be near his home and friends. In Massachusetts the law provides that cities shall establish and maintain tuberculosis hospitals, which must be approved by the State Department of Health. The law also provides that towns may, and, upon the request of the State Board of Health shall, establish such hospitals. For every patient received at these hospitals the State grants a subvention of $5. Failure to comply with this law is punishable by a very considerable fine. The State Sanatoria are under the direction and control of a board of trustees appointed by the Governor, and the consumptive hospitals and dispensaries are under the general supervision of the State Health Board.

For all its tuberculosis work the State of Massachusetts is spending annually somewhat over a million dollars; and the private expenditures for the same purpose amount to over $300,000 yearly. There is now but little difficulty in obtaining from the Legislature this large yearly appropriation for the extended tuberculosis work the State has undertaken. Education has done its work. The people recognize the economic necessity of effective tuberculosis prevention and control and are willing to pay the cost.

I think we all would agree that these five lines of attack are fundamental in comprehensively dealing with the tuberculosis problem, and that they can best be effected with a continuity of purpose under State authority and control. The State has power to command and enforce obedience; and one directing body can most effectively coordinate and systematize the various kinds of tuberculosis work. Moreover, the State is in the position to obtain the requisite means when it has once awakened to the importance of the problem as an economic measure.

The special methods which the State would employ in carrying out this work will naturally differ under differing conditions. Large cities, for example, can generally be left to themselves to efficiently deal with their local tuberculosis problem, as New York and Boston and others are doing. In the agricultural States certain sections, as counties, can unite in providing accommodations in consumptive hospitals for their advanced cases. In sparsely settled areas there might be some method of medical inspection by a visiting physician, in place of a dispensary.

Each State must work out its own method of conducting its campaign, keeping in view the cardinal objects to be attained: Education; opportunity for the examination of suspected cases, and provision for active cases of the disease, either in the curable or advanced stage; in any case, it is essential that there should be a State administrative body to direct and supervise the work, and with ample power to enforce its decrees. When the people of the State once recognize the extreme importance of controlling tuberculosis, both as an economic as well as a health measure, sufficient appropriations for the purpose will be forthcoming; they will realize that public "health is purchasable" and pays a good rate of interest.

* Part of a discussion at the meeting of the National Association for the Study and Prevention of Tuberculosis, Seattle, June 14, 1915.

ANALYSIS OF A CLAUSTROPHOBIA.*

By C. P. OBERNDORF, M.D.,

NEW YORK.

CLINICAL INSTRUCTOR IN NEUROLOGY, CORNELL MEDICAL SCHOOL; ADJUNCT NEUROLOGIST, MONTEFIORE HOME.

THE conception that sexual traumata during childhood may *per se* in later life become the etiological factor in the development of a psychneurosis has been abandoned, but it is gradually becoming firmly established that the resistances which they engender at the time of their occurrence are often prolonged and remain dynamically operative throughout life. The individual's reaction to such occurrences corre-

*Read before the Section on Neurology and Psychiatry, N. Y. Academy of Medicine, April 13, 1915.

sponds to the speculations which may have been long previously engrossing his attention and when in adult life he faces a similar situation, unless the resistances have been successfully overcome in the course of the evolution of his personality, he may develop a neurosis as an unconscious solution of his difficulties.

That the situation which confronts him bears any resemblance to the one encountered years previously is, of course, not recognized by him. However, not infrequently it happens that we conceive the impression of having seen a thing or having been in a certain situation at some antecedent time, without being able to verify this impression by recalling the exact circumstance to memory. Grasset, in 1904,* explained this phenomenon of "deja vu" on the basis that some antecedent impression had been unconsciously received, but only became conscious under the impetus of the new and similar situation. Freud, from analytic studies, especially in attempting to explain the very frequent circumstance of patient's remarking that "I have already told you this before," though it is the first time that the subject has been mentioned during the course of an analytic treatment, arrived at a like conclusion.

From similar reasoning it is probable that when a person reacts to a certain situation with a very strong affect which he cannot explain, examples of which occur daily and find expression in such utterances as "I don't know what there is about this or that place but there is something which I don't (or do) like," that this too, is a reproduction of an affect which really belongs to something else previously experienced but which is displaced into the present and which the person cannot identify as connected with the subject before him.

The case which I am about to present is reported not primarily on account of the successful therapeutic issue of the analytic treatment, but to show how the resistances of childhood persisted throughout the patient's life and unconsciously dominated it, and how the affect of an early experience reappeared in a similar situation when the patient for all his twenty-five years had not advanced far beyond his psychosexual attitude at five or six.

The patient, a stationary engineer, an American of Irish parentage, aged twenty-seven when he first consulted me in March, 1912, complained at the time of nervousness for the preceding five years and a fear of three years' duration which developed whenever he entered a crowd or felt himself surrounded. Inasmuch as his work as a stationary engineer in subway construction necessitated his entering a shaft, after a long struggle he was forced to cease work on account of his obsessive fear, and for four months prior to the undertaking of treatment had remained idle. In writing of his trouble at the time he stated that he had "remained at home, slept a great part of the day, or lounged about in a half-sleepy fashion and put in awful days, because he did not know what was the matter with him." The apathy and indifference in the early days of the treatment raised the question in my mind as to the possibility of an incipient dementia precox, but the continuous and appreciative insight subsequently dispelled this consideration.

*Grasset: *Journal de psychologie norm. et pathologique*, I., 1904, cited by Freud Über Fausse Reconnaissance, *Zeitschrift für Arztliche Psychoanalyse*, Vol. 2, No. 1.

His own statement of the onset of his difficulty, written in April, 1912, is as follows: "About three years ago, while at the American Theatre, I became startled when the performance was half over. My first impulse was to leave and go home, but I resisted this feeling and remained. It annoyed me very much, for I could not understand the reason for feeling so. At first I thought it was from smoking—or from coffee. A few months before, while at work, which required heavy lifting, I was afraid that I would rupture myself and had the same 'startled feeling.' It passed away."

Of course the patient had on other occasions visited music halls and the theater, where he approved or disliked the performance according with the general standard of criticism which we all employ, *i.e.* whether it harmonizes or clashes with our own mental attitude. On the particular evening when the patient reacted so intensely, the presentation to the average person in the audience probably did not vary from the customary routine of the cheaper grade of vaudeville, and the patient himself could discover no satisfactory reason for his affect. The usual explanations, smoking, hard work, etc., to which he attempted to ascribe his peculiar sensations, fell away one by one as being inadequate.

From the analytic point of view there must have been some individual significance in the circumstances which revived some of the patient's earlier problems. So, too, his fear originating at the time must have been a defense against something (or its equivalent) which the patient desired and yet felt unable to undertake because of conflicting and counteracting tendencies.

Let us first review the situation in which the patient found himself when his neurosis became urgent and also his life history.

One might readily state that he typified the more intelligent class of American workman—capable, reliable and skillful, with a comprehensive grasp upon general and strictly personal problems. He was residing at home with the family which consisted of father, several sisters and one brother. As the family, all of whom were adult workers, contented themselves with a scale of living corresponding to their income and were thoroughly comfortable, no material difficulties existed. The patient's own earning capacity up to the onset of his illness quite sufficed for all his individual needs. On the other hand, at the time that the neurosis developed, he was seriously contemplating becoming definitely engaged to a Miss B., one of his sister's friends with whom he had been well acquainted for some time.

The patient, who was born into a workingman's family as the sixth child, spent his early days in a small village in New York State, where he completed a common school education at fifteen years, after which he entered his present trade. As a boy he showed proficiency at school in history, spelling, and memory work, was well liked by his comrades, and active in outdoor sports.

Very brief conversations soon disclosed the strong influence which the Catholic Church had exerted almost from infancy upon the patient's emotional and moral life. So far as I could judge, it has been the most powerful single factor, with the exception of an early developing mother love, with which it is indeed closely connected. Outside of her numerous household duties, the mother's only interest centered in the church, priests, and the morality which the church represents.

The attachment for the mother soon assumed the form of an attempt to please her by imitating her devotion to Catholicism and reverence of the priest. Very early it led to the following little symptomatic habit: One day an old man in the village was casually singled out by the mother as being a very "good, pious man." The only tangible characteristic about this old man which to the six-year-old boy's mind seemed to distinguish him from other and perhaps less praiseworthy mortals, was his habit of sauntering slowly along the road with his head slightly bowed and his hands clasped behind his back. Then, in the hope of obtaining recognition and praise from his mother, the little fellow would pace solemnly up and down the front porch for hours at a time in the decrepit attitude he had observed in the old man, and it was a source of no small, though secret, disappointment to him that the mother never discovered the significance of his efforts.

The first confessional, to which the patient was taken at the age of six, so impressed and awed him that he wept for an hour after leaving the church. Early religious instruction, especially the ten commandments, which were among the earliest knowledge acquired at the Sunday School he attended, confused and mystified him. The adultery commandment, which he inferred in some vague way to be connected with sex, especially puzzled him, as, for that matter, it does practically every child.

The precocity which the patient showed in his religious and intellectual life found the usual early expression in the sexual field, as exemplified by two incidents which the patient recalled in the course of associations to his dreams, which so often reverted to the scenes of his childhood, and which practically embody the gist of his neurosis.

His boon companion from the age of six to twelve was one Jimmy, a mischievous youngster, who acted as leader and instigator in all their youthful escapades. Jimmy's aggressiveness and activity to the patient represented an independence, manliness, and heroism, which he sought to imitate and exceed. When Jimmy began to extend his education of the patient to sexual matters, informing him that he had had coitus with a certain neighbor's daughter, a child of six, the patient, not wishing to be excelled by Jimmy in manliness, in spite of the conflict of such an action with his already deeply imbued moral sense, led the girl into the woods where he intended to assault her. Just as he was about to begin the act, to which the child made no resistance, the thought that he heard someone coming caused him to hurriedly abandon the attempt.

A short time after this, under Jimmy's tutelage, the two boys took another little girl to a room where she posed nude before them. While they were being thus entertained, the patient, much conscience stricken and fearing discovery, again thought he heard someone approaching, and fled.

The patient's subsequent sexual life consisted of a series of struggles between his cravings and his religious ideals. From the age of eight he became overscrupulous in all his dealings with his friends and in his attention to school work.

At about the age of ten he became convinced from comparison of his penis with that of the other boys at the swimming pool that it was too small. Later the appearance of frequent and prolonged erections and emissions, which he regarded as supernatural visitations, further tormented him. They also tended to intensify his curiosity, but this he roundly refused to satisfy, and walked righteously away from the back-yard fence conferences which his companions held, notwithstanding an ardent desire to participate in them.

A period of unusually frequent masturbation began at 15 years and continued until 24. The act was accompanied by elaborate fancies of coitus with many different girls and women, most often in the woods, where the patient loved to allow his reveries to wander. The practice continually caused him great remorse from its religious and moral aspect, and at the same time awakened grave fears for his physical and mental health, based upon knowledge gleaned from literature of advertising physicians. On the other hand, he could have had frequent opportunity for intercourse out of wedlock, had he desired it, with several girls of his acquaintance.

When, at the age of 15, the patient left his native village for the city, where he had secured a position, for some time he commuted daily, and on these trips, a certain large, rough-mannered man, in coming through the train would, in passing down the aisle, make a playful attempt to seize the patient's genitals. Although the patient claims that he became alarmed lest this man should discover that his penis was small, curiously enough he made no effort to avoid a repetition of the alleged annoyance. In fact, although he did not smoke, he took a seat each day in the smoking compartment through which this man was wont to pass in departing from the train, and what is more noteworthy, he made no attempt to leave his seat until the man had passed him.

Although the patient left his home at seventeen to locate in New York City, the family did not join him here until some years later, and the patient describes the arrival of his mother in the city as the happiest day of his life.

A short time thereafter the mother was stricken with a hemiplegia, which the patient was informed by the physician in charge, to be due to a disease of the brain. This immediately gave rise to the thought that he would become insane, for he reasoned that as both insanity and hemiplegia were diseases of the brain and his mother suffered from one of these diseases, and that, as, on the other hand, insanity was reputed to be transmissible, he would suffer from insanity, a brain disease, on the grounds of inheritance. This naturally increased his already severe mental distress and his mother's death a short time after the stroke, before which she did exhibit some of the minor mental disturbances which sometimes accompany cerebral hemorrhage, perturbed him more than ever, and the neurosis soon assumed its active form.

Analysis.—When a patient comes complaining of a morbid fear it may safely be assumed that the fear represents symbolically some sort of a protective measure which is double in its function. In the first place it represents a protection against an unconscious wish and has a positive aspect in that it tends to the maintenance of a condition or situation where consciousness is most easily satisfied. In its negative phase, it represents the negative of an unconscious wish to indulge in something actual or symbolically substituted or represented, which the patient would like to do or experience, but which is impossible for him because it interferes with his conscious desires. Unless there be some

desire, there can be no pathological fear. Let us take as an example a man who fears that he may steal. Unless he had some unconscious desire to steal or do something which stealing represents, he would feel in no danger at the idea of stealing. The man who develops such a fear cannot admit to his consciousness that he should harbor such unworthy thoughts.

On such a basis, a fear of closed places must represent the negative of an unconscious wish; that is, the patient desired to enter closed places, but wished for the sake of conscious qualms to be protected against such an eventuality. The clues of its origin are found in the history and corroborated by the fancies. It arose at a time when the patient was considering entering the bonds of matrimony, it supplemented and to a measure supplanted a fear of impotency.

In his description of the onset of the claustraphobia, the patient recalls having once previously experienced the "startled feeling" when he thought that he had ruptured himself. Now to him, as to many other persons who are ignorant of the cause of hernia, rupture is intimately associated with ideas of sexual disorders. I recall having spoken with the captain of one of the famous university football elevens, who had ruptured himself, but had failed to report it to the trainer of the team because he believed it to be a disreputable sexual malady. To our patient rupture meant impotency and the startled feeling at the time of the strain to which he refers, may have had an associated significance with the one which occurred at the theater.

In studying a fear of impotency, such as existed in this case, it is not sufficient for the psychoanalytic investigator to attribute it to the most convenient etiology, that is, excessive masturbation, without examining the content of the masturbation fantasies, to determine whence the fear of impotence arose and what it means to the person entertaining it.

From associations to his dreams were uncovered the two childhood experiences, already mentioned, with the hallucinatory warning of "somebody coming," which served to interrupt he patient in his transgressions. Such an hallucination seems best interpreted as a censor of the unconscious, protecting the patient from the fulfilment of a strong desire to demonstrate his potency—in other words it reinforces the more powerful force, the primal tendency to remain unsullied. So, too, we may theoretically explain the repetition of the phenomenon on the occasion of his second temptation—in the closed room when the little girl posed.

The patient's fear of impotence which he developed at the age of puberty, when most of his companions were beginning to indulge in intercourse—a rather common practice in many of the rural districts—may now be regarded in a new light. It, too, is a defensive reaction against an unconscious wish to be impotent. The fear of impotency, which makes him afraid to test his potency, is a product of his wavering position in regard to physical chastity and tends to reinforce his faith in his religious and moral scruples.

A similar interpretation is accountable for the patient's tolerance of the sexual episode in the train for so many months—a thing which so far as his conscious reaction went, aroused his resentment and indignation. The practice of the rough-mannered man, which he abetted, unconsciously afforded him pleasure by reminding him of the diminutive size of his penis, which in turn fortified him, by the assumption of a physical disability, against the temptations of the city, which were magnified in his mind by his removal from the restraint of his mother's environment.

The period of overscrupulosity in home and school duties, which the patient mentions, may be regarded as compensatory for his apostasy to the religious tenets in regard to his sexual practices.

By analogous reasoning a fear of closed places must represent a desire to enter some type of closed place, an idea which is not compatible with a stronger wish to remain in the open. In other words, the fulfillment of the patient's urgent desires to be where his conscience tells him he should not be, that is, indulging in sexual relations, is resisted and prevented by the fear. Thus it is supplementary to the fear of impotency and furnishes the same type of protection—namely, to keep the patient chaste, pious, priestlike, faithful to ideals of his recently deceased mother.

Symbolically, on the other hand, it expresses his desire to avoid another form of binding or enclosing condition, namely, marriage, and reinforces the final results of the longstanding protective fear of impotence. It furthermore typifies the patient's unconscious desire to cling to satisfying polygamous fancies rather than face the actuality of his uncertain adaptability to a monogamous union.

What explanation can be found, however, for the origin of the claustrophobia in the theater at the time when it occurred? Of course, his own impending engagement and the death of his mother would furnish two palpable factors for the need of additional support to keep the patient free from any alliance involving sexual indulgence. However, something infinitely more potent must have existed in the theatrical presentation which responded to earlier affects of the patient to satisfactorily account for the fear. Closer investigation disclosed the fact that the feeling originated during a posing act by Maud Odell, "the English beauty," in which the actress appeared in fleshings in a woodland scene. Thus the patient found himself enclosed in an orchestra row and confronted with a pictorial combination of the two scenes of his childhood transgressions—so oft repeated and embellished in the fancies of adult years—and an unconscious identification occurred with a repetition of the desire to escape from the situation.

The fear would thus represent the same type of protective measure as did the hallucinatory warning of "somebody coming" at the infantile period when the patient's resistances were first aroused. Its extension and displacement to other spheres than the theater is a common and readily comprehensible phenomenon. It has been my experience that when one fear accompanies another, as in this case the fear of impotency and the claustraphobia, they are apt to be merely diversified expressions of the same general unconscious trend.

The unconscious passive homosexual component, which the patient's psychosexual attitude represents, has not been emphasized in this presentation, though its existence seems quite obvious.

As the psychoanalysis of any patient progresses, in a case where factors which have had their effect in the production of the neurosis are still operative, *e.g.* in this case, the inflence of Catholicism upon the mental habitude of the patient, a clash between these interests and his altered conception becomes inevitable. When the equation is a per-

sonal one with some member of the patient's household or family, who harbors a complementary attachment to the patient, the condition becomes one of the most difficult of the many problems which the analyst encounters. So in this instance, where we were led into a province which the Catholic Church regards as its own, and for which it partially provides by the confessional, and where the priest still exerted a strong control over the patient, some reactionary opposition might have been expected from this source. However, when the nature of our conversations began to arouse the scruples of the patient, he consulted the priest, who in this instance as on two other occasions in my experience, where psychoanalysis and Catholicism seemed antagonistic, supported the physician, eliminating a source of resistance which might have prolonged the treatment for many months.

In this connection, in drawing the distinction between mental catharsis (with which the psychoanalytic movement had its origin) and a psychoanalysis, I might mention that practically all the peccadillos of the patient, if such they may be termed, had been confessed and forgiven from time to time after their occurrence. The reason why the solace from this quarter was transient and unsatisfactory is almost self-evident, for the patient himself did not realize where the defect lay and could not confess what was unknown to him.

When it became clear to the patient that his neurosis represented a defense reaction elaborated as the solution of his psychosexual difficulties and the symptoms had disappeared, I was interested to know how he would solve the actualities which confronted him. On the whole, I am inclined to adhere to that faction of the psychoanalytic school which contents itself with the presentation of unconscious influences to the patient's consciousness and allows him to select whatever course he considers best.

Three solutions of his situation were open to the patient, all compatible with peace of mind. I believe that it is entirely consistent with mental health for an adult to cling to an infantile ideal, provided that he is entirely conscious of the nature of his adjustment, and also believe that a person may remain sexually abstinent physically without being inevitably doomed to become subject to an anxiety neurosis. Thus the patient might remain loyal to his childhood chastity conceptions, with a mastery of his sex cravings, or indulge sexually outside of wedlock, or marry.

A recent interview with the patient, whom I had not seen since March, 1913, when the treatment begun in April, 1912, was concluded, showed that he had an excellent grasp of the factors figuring in the development of his neurosis and that he had arranged his life, as one might have been inclined to infer from the foregoing analysis, by adherence to his original concept toward chastity. He has neither married nor indulged, but being entirely conscious of his adjustment, is without conflict, and since his discharge as cured in March, 1913, has been working steadily and contentedly far underground in the subway shaft.

249 West Seventy-fourth Street.

The Horse as a Meningococcus Carrier.—Loreto Mazzetti isolated the meningococcus from the nasal mucosa of horses during an epidemic of meningitis last January and February, among the troops garrisoned at Capua. He calls attention to the horse as a possible meningitis carrier.—*Riforma Medica.*

THE FALLACY OF EUGENICS.

By A. L. SWEET, M.D.,
Geneva, N. Y.

The term Eugenics, which meets our eye so frequently in these days, is derived from a Greek word meaning "well-born," and those who are interested in the movement are laboring to establish such racial conditions as will assure to every human child the priceless privilege of being well born. That every infant should have this fortune no reasonable individual will deny, but to the thoughtful student there are so many difficulties in the way of its accomplishment, that he may well turn away in discouragement. But granting that the kindly fates have presided at his birth, what manner of man will he be as his life-history unfolds through the pregnant years? We may assume that although the infants of the race (if equally well born) start with equal equipment for the struggle, as they rush from the starting point, their characters will be infinitely varied. Some will grow into poets, statesmen, and philanthropists—the most glorious assets of their country—while others will recruit the ranks of the vicious and criminal; while others still will be the nonentities—the cumberers of the earth.

What eugenics is concerned with is the question—what were the determining factors that shaped these lives? Were they the racial qualities of their ancestors that propelled them irresistibly in a given direction, or were they molded by their surroundings after they were ushered into this life. Samuel G. Smith, an influential writer upon social subjects, says that there are three principal factors in the life of every human being, viz., Heredity, Social Relationship (by which he probably means environment), and Personal Choice, and it is necessary to consider what each of these contribute to the individual ego. Heredity will probably suggest itself first to most minds and occupy the largest place in any discussion of this kind, but heredity may mean all things and it may mean nothing. Of course there is nothing (except perhaps acquired ability) which may not be handed down from one generation to another, but what individual characteristics *will* be transmitted, no man can predict. Even in the animal world, where the breeder may control conditions at his will, he frequently finds himself baffled and disappointed. There is a very interesting thing in connection with horses. The breeders have learned that although the sire may be absolutely perfect in every way, he may not be able to impress himself upon the next generation. He lacks the quality which they call "prepotency," and lacking that he is worthless in the stud. It would seem to be an unquestioned fact that the continual breeding from the fastest individuals would bring racers, but even here numerous disappointments await the breeder; on the other hand there sometimes come results unexpected and unaccountable that bring gratification in their train. The following instance came under my own observation. A few miles from where I lived on Long Island there was a man who had a barren farm on the Sound. He made a race course by clearing away the boulders, etc., and used to amuse himself by speeding some of the colts that he raised. Everybody ridiculed him, but one of his colts indicated very early that he was different from the rest, and soon developed a marvelous speed. He was the famous "Rarus," one of the finest horses ever raised in this country, and for which Robert Bonner paid a princely sum. His sire was raised on the farm,

and the dam was one of the old-fashioned, speckled, grey mares. Where did he come from? I am unable to recall any instance where a great man has been succeeded by a posterity at all equal to himself; on the other hand there are many instances where there have issued from sources most unlikely to produce anything of the kind, men who by their intellect and genius have enriched the world and become the symbols of their age. Shakespeare's father was a wool-factor, Burns' a peasant, Carlyle's a stonemason, Lincoln's a humble and inefficient man. One would expect that from the union of the Brownings something almost superhuman would emerge, but nothing of the kind happened. Of course every child born into the world has, in the direct line of his ancestors, virtuous and vicious antecedents. What shall determine his character? To my mind one of the saddest things about this whole subject of heredity is that, however virtuous and intelligent the immediate parents may be, their offspring may show all the diabolical instincts of some far away vicious ancestor. This is a matter of common observation. I have in mind several instances of this kind where boys born under the most favorable circumstances betrayed vicious instincts as soon as they were able to manifest any individuality at all. Before leaving the subject of heredity I will submit a comparison which is generally quoted by the apostles of heredity; it is that of the infamous Jukes family and that of Jonathan Edwards the distinguished American clergyman, not one of whose family was ever convicted of crime and most of whom have occupied positions of honor and trust.

Max Jukes (born 1720); 1,200 descendants identified: 300 in the poorhouse, 300 died in childhood, 440 viciously diseased, 400 physical wrecks, 50 notorious prostitutes, 7 murderers, 60 habitual thieves —averaged 12 years in jail.

Jonathan Edwards (born 1703); 1,394 descendants identified: 295 college graduates, 1 Vice-President, 3 United States Senators, 12 college presidents, 65 college professors, 60 physicians, 100 clergymen, 75 army and navy officers, 60 prominent authors, 100 lawyers, 30 judges, 80 public office-holders.

This is certainly a startling and seemingly absolutely conclusive exhibit, but when we look behind these figures, and see in imagination the setting of these two families, much of its significance will disappear. The woman, whose name was Jukes, was a dissolute and shameless character, living in the slums of London, and the man who was associated with her was of the same character as herself. When children came they were reared in an atmosphere of depravity—where purity and virtue were absolutely unknown. They probably never emerged from the underworld in which they were born, except to be taken to the nearest gaol for some crime. What possible chance was there for them to attain to a virtuous life? On the other hand the Edwards parents were exemplars of the human virtues—singularly so—and the children were born into an atmosphere of Christian courtesy, piety, and all graciousness. They were as ignorant of vice as the other family of virtue.

I wish here to give a brief quotation from Buckley, the great English scientist, although it is rather out of its proper place: "We often hear of hereditary talents, hereditary virtues, and hereditary vices; but whoever will critically examine the evidence will see that we have no proof of their existence. The way in which they are commonly proved, is in the highest degree illogical, the usual course being for writers to collect instances of some mental peculiarity found in parent and child and then conclude that the peculiarity was bequeathed. By this mode of reasoning we might demonstrate any proposition, since in all large fields of inquiry there are a sufficient number of empirical circumstances to make a plausible case in favor of whatever view a man chooses to advocate. But this is not the way in which truth is discovered; and we ought to inquire not only how many cases there are of hereditary talents, etc., but also how many there are of such qualities not being hereditary. In the biological field no discovery has yet been made of any certain law of inheritance even in the smallest matter of physique and appearance. An athlete does not always have athletic sons, but he often has none at all, and so with other matters. As to the greater matters of intelligence and virility *nothing whatever is known.* What is the process by which man has evolved so far, and what has the experience and observation of thousands of years taught us? What is that method? It is called falling in love. What is this mysterious something which brings young people together? Why does the man pick out one woman for his mate, and why does she respond to his call? Is it not nature's method to get what she wants—children? Love is life, love makes the world, love keeps it—only to love shall it be given in the future. It is the soul of art, of music, of literature. The Eugenist would banish all this—he would have a commission or board and select according to his ideas two individuals and mate them as one would poultry—no word of love here—love that is the motive power of the world. It is the purifying and regenerating power. Even those whom the Eugenist calls degenerates would stand a better chance of having intelligent children than the best mated eugenic couple."

It has been well said that every child is a member of the whole community, and his future will be determined to some extent by his surroundings, and there are as radical differences in communities as in individuals. I have in mind a village where there are more college graduates than in many a place much larger, and the whole atmosphere is in the direction of culture and education. Now it is perfectly evident that in a community like that the trend of a boy's mind would be in the direction of the higher and better things. Of course the deepest impress upon his nature comes from the home, but his civic surroundings will not be without influence. He comes into the world without knowledge or character, but as soon as his eyes are open his education begins, and every thing which he comes in contact with furnishes something toward it. It is difficult to imagine that if Shakespeare or Carlyle, or Cromwell—all of humble origin to be sure—had been born in the slums of a great city, they would have fulfilled their destiny. Since this matter of environment has claimed the attention of reformers thousands of children have been taken out of the slums of the cities and placed in comfortable Christian homes, and they have developed as favorably as children born under more favorable conditions. The eugenist aspires to the perfect child and believes that the rest may be left to his environment, but I think I have shown that nothing can be predicated in regard to his future. A writer in the *Outlook* expresses himself somewhat pessimistically along this line: "The blood of the noble, the wise, the beautiful, the good,

the base, and the cruel flows in the veins of us all, and who shall determine in advance which of our millions of ancestors will be repeated in any of us? Whether the story that Dr. Johnson, on seeing a thief riding to Tyburn, said 'There, but for the grace of God, goes Samuel Johnson!' be apocryphal or not, the sentiment is sound and the assumption pregnant with meaning. The environment is nothing and everything. It cannot bring out qualities that are not there, but all that is there, good or bad, will respond to its call. The surroundings of man, moral and material, which we may understand if we will, are far worthier of our consideration than the germ-plasm of which we know little, and perhaps even that little wrongly."

Conceding the dignity and importance of the work of the eugenist, how is it to be accomplished? Some of them, like others in the State, think that legislation might avail, but there are many reasons why that would not succeed. It has been tried in some States—two, I think—and the immediate result was to diminish the number of marriages, a result which would work infinite harm. But there are other results, people would evade the law by secret marriages, and consequently would eliminate children. Even if a pair were found to be physically competent, there might be other reasons why they should not marry. The only way to improve the breed of babies is to improve the fathers and mothers. The mothers are pretty good now and always have been, and that has been the salvation of the race. They are the conservators of the home. There are thousands of homes in this country where children are being reared to become good citizens, where the father has hardly more responsibility than the cat that purrs upon the hearth. Of course let us have fathers as good as we can, but it is *vital* that we have good mothers. We may philosophize as much as we like, but the fact remains that the good or evil destiny of a nation will depend upon the character of the mothers. There are many conditions which are developing at the present time which must unsex and unhome our mothers and sisters. The struggle for political prominence and the widespread entrance into industrial pursuits must destroy in some degree the taste for the simple and quiet joys of domestic life. There is an atmosphere about a modest, true woman, subtle and sweet, which no one can define—but which we all feel. Life in the store, or shop, or office does not seem to be the best preparation for home life. The following from an article by Dr. Maud Glasgow in the MEDICAL RECORD expresses better than I can the thought in my mind:

"Considered from this aspect, the wholesale employment of women is an unmitigated evil. It goes without saying that if women refuse to bear and bring up healthy children they will not fulfil their physiological duty, and the nation must suffer. Woman's participation in industrial occupations has during the past decade effected great transformations, which have not tended to the advantage of her productive and reproductive strength. In short, industrial and professional work, to a great extent, unfit a woman for motherhood and domestic life, as is plainly shown by the unwillingness of the present generation of women to undertake the duties of motherhood and home. In addition it is distinctly against the interests of the race, mentally and physically, that a mother should engage in outside work. Infants should be breast-fed, which is impossible if the mother is working away from home. When young they should be constantly under the eye of the mother for the sake of their physical, mental, and moral health, and if this is not done they, and ultimately the race, will suffer harm. At the present time a lamentable waste of women is going on, and the matter requires immediate attention. The fact must be recognized that the rôle of woman has changed, that this change is not for the better—at least, not from a medical point of view—and while allowing that the old state of affairs has gone, never to return, at the same time steps should be taken to endeavor to deal with existing conditions in such a manner that the race will suffer as little as possible. A necessary movement in this direction is to find out exactly how matters stand by initiating measures for the compilation and publication of national and international statistics relating to the participation of women in industrial prusuits."

Is there then no place for eugenics in the world? Yes, but it is simpler to call it common sense. The animal breeder has learned that the only way by which he can improve his stock is the tireless selection of the best specimens to breed from. The same laws apply to the human family. The constant union of individuals in approximately perfect physical and mental condition would by the nature of things constantly improve the race. But, as Professor Buckly says, you cannot mate human beings as you would poultry. As soon as you attempt to dictate to human beings to whom they should unite themselves, you encounter the strongest and most imperious characteristic of their nature—love has no use for eugenics. I agree with the eugenist that the diseased, the vicious, the imbecile should be eliminated and not allowed to perpetuate their kind. The Great Apostle to the Gentiles was the first eugenist, and one of his sayings is the most comprehensive that ever fell from the lips of man, "Know ye not that your body is the temple of the Holy Ghost?" If every one realized the significance of these words and acted upon them as if they applied to himself, many of the social problems would be solved and the rising generation lifted up into an atmosphere of purity and self-denial.

CHRONIC APPENDICITIS—ITS RELATION TO CARDIO- AND OTHER NEURO-SPASM.

By T. A. KENEFICK, M.D.,

NEW YORK.

THE early advance in medical knowledge of appendicitis gave enthusiasm to surgeons to perfect their technique and taught physicians to recognize at least its acute form and to promptly summon surgical advice and assistance. We are not shrewd enough, however, in detecting cases in their subtle form and chronicity through the veritable chaos of symptom-complex, and also from a lack of a refined technique in palpating the abdomen.

With a negative history and absence of local symptoms we can be easily misled, when proper digital pressure would disclose a quick and vigorous response to pain almost pathognomonic. Resembling an explosive bomb it may lie in the pelvis quietly prepared for a sudden and often fatal attack, this state of chronicity being questioned and often ridiculed if suggested as being the cause of remote nervous symptoms, especially when the pathway of nerve communication is not clearly understood.

Holding an inflamed appendix responsible for disturbance or even reversal of certain functions may appear as a stretch of the imagination, but a mental physiological picture of the apparatus in motion will help to interpret a rather complicated phenomena.

As we already know there are involuntary muscles performing special functions in the economy, of which peristalsis of the esophagus and that of the stomach are typical examples, depending upon a central force for their power, speed, and rhythmical action. We must also bear in mind the fact that the cells of the cerebrospinal system, as a result of their metabolic interchange originate and distribute an element or physicochemical current to these muscles, in fact to all organs, secretory and otherwise, for their physical motion and even chemical balance. Emanating from the common stock of the universe, this force is transplanted and inherent in various degrees in man, responding to our physical laws of supply and demand during tissue waste and structural repair, supplying also a sympathetic service between these organic functions and their varied secretions. Muscles deficient in glycogen appeal through afferent impulses through the suprarenal glands to the storehouse in the liver. Damaged tissues from operation or trauma also send impulses to the vasomotor center so constant and active as to produce finally a state of protoplasmic exhaustion technically termed shock.

The deep and mysterious functions of ductless glands and their wonderful power for good when properly prescribed also testify to this element in our bodies, the presence of which in health we are absolutely unconscious. The purpose here, however, is to show the generation of similar impulses from a local irritation in chronic appendicitis, along paths independent of the spinal system, to involuntary functions causing spasm and even reversal of their normal action, and to show also that these phenomena can occur anywhere along the course of this particular branch of the nervous system from such a local irritation.

These spasms, owing to the method by which they are produced, may rightly be termed "traction spasm," as the following reports of cases illustrate:

Case I.—M. O., male, American, age 50, came with a diagnosis of "false angina," described by the patient as seizures with a sense of suffocation, fear of impending death, and exhaustion. They came without warning, frequently independent of diet, and also of physical or mental exercise, but never when lying down. Family history excellent. Past history negative. Lives a simple life in a small-sized city. Physical examination negative, including nervous system and kidneys, but deep pressure directly over the appendix region brought out intense pain which manipulation could radiate in different directions. Chronic appendicitis was diagnosed as the cause of traction spasm in a limited area of the upper bronchi. Roentgenograph confirmed the findings in the appendix and operation to prove the nerve connection was advised, but declined.

Case II.—Female, age 45, Russian, married. Patient from a New York City Clinic, kindly referred for verification of the spasm theory. Complained of esophageal spasm during deglutition. Bland fluids would sometimes reach the stomach, but slightly irritating fluids or a bolus caused a spasm with which reversal of muscular action and ejection of contents occurred. Physical examination was negative with the exception of an excessively tender appendix. Diagnosis: chronic appendicitis with esophageal traction spasm. Operation was advised offering a chance of relief, but declined. Roentgenograph confirmed the diagnosis of chronic appendicitis.

The following is Dr. A. J. Quimby's interesting report: "Parts examined: Esophagus and appendix. There is interference at the cardiac end of the esophagus which is intermittent. Opposite the eighth rib posteriorly there is a sack projecting to the right posteriorly from the esophagus about 3 cm. long and 2 cm. wide. Appendix small, distorted and kinked."

The development of a sac or diverticulum by pressure or bougie manipulation is not unusual in these cases.

Case III.—Miss P., aged 22, single. Family history negative. Healthy up to two years ago, when persistent vomiting began directly after taking food. Three months after she had two separate attacks of acute appendicitis within two months. She was taken to a hospital where each attack subsided. The vomiting continued with great loss of flesh and strength. Within a month an exploratory incision was made for examination of the stomach but nothing abnormal was found. The appendix was "felt" and reported unusually long but was not removed. After recovery from the operation she was exhibited as a rare case of "tetany of the stomach." Psychotherapy was advised and practised without relief. Four Roentgenographs were made with a negative report in all. She was referred to me at this point for physical examination and verification of the spasm theory. I found her underfed and thin but otherwise healthy, with the exception of the characteristic sharp pain on deep pressure over the appendix. A diagnosis of chronic appendicitis was made and given as a possible cause of the spasm which reversed the normal peristaltic action of the esophagus and stomach. A roentgenograph confirmed the diagnosis of chronic appendicitis. Appendectomy was advised with the hope of relieving the irritation and indirectly the traction spasm. Life was so miserable for the patient that in this instance it was accepted.

April 15 a thickened and diseased appendix six inches long was found coiled and attached along the posterior wall of the cecum and removed. She made an excellent recovery from the operation, had the usual vomiting following ether, but since then, a period of two months, she has retained all food, gained in health, strength and weight, and to all appearances can safely be said to have regained her former normal condition.

This irritation or traction spasm originates at some particular attachment of the appendix to a branch of the mesenteric plexus and reaches the musculature of the stomach by way of the mesenteric and celiac plexus as follows A. Hepatic plexus and plexus gastroduodenalis to pylorus. B. Plexus gastroepiploica dextra to pylorus and region of lesser curvature. C. Plexus gastrolienalis to fundus and region of greater curvature. Afferent impulses in general pass from an inflamed appendix to the mesenteric ganglia, suprarenal ganglia, vagus to medulla and cortex independent of the spinal centers.

I am indebted for physiological proof to Prof. Russell Burton Opitz of Columbia, who had, when I consulted him, just completed a series of animal experimentation on this same subject. Curiously enough, we had both been working independently, one on the animal and the other on the clinical side, so that, when a scientific explanation was needed, I was cheerfully given the physiological proof and the route of the message in these particularly interesting cases. I am indebted also to Dr. A. J. Quimby for roentgenographs and interesting reports, to Dr. John J. McGrath for his services in the case operated upon, and to Dr. Hofheimer of the Mt. Sinai Clinic for the opportunity of clinical investigation.

78 East Fifty-fourth Street.

Intestinal Hemorrhage in Typhoid Fever in Childhood.—Bonaba in reporting a fatal case of this condition in a child twelve years of age alludes to its extreme rarity, his being the first that occurred in a series of 240 cases of typhoid fever in his hospital pediatric service since 1908.—*La Pediatria Española.*

CHEMICAL AND PATHOLOGICAL OBSERVATIONS IN A CASE OF MERCURY POISONING.

By MAX KAHN, M.D., Ph.D.,
VERNON L. ANDREWS, M.D.
AND
J. H. ANDERSON, M.D.,
PITTSBURGH, PA.
(From the Laboratories of the Western Pennsylvania Hospital, Pittsburgh)

THERE has recently appeared a paper by Rosenbloom[1] in which attention is again called to the distribution of mercury in the tissues after bichloride of mercury poisoning. While a number of such analyses[2] have appeared in the literature, none of them (except the one of Rosenbloom) has been complete, and most of them were unaccompanied by any pathological reports.

The patient, a Greek, took from 25 to 50 gms. of bichloride of mercury with the intent of committing suicide. He had all the symptoms of acute mercurialism, and promptly went into a condition of shock and finally coma. The Anderson operation[3] was performed, and the large bowel washed with gallons of saline solution. These washings were collected and analyzed for mercury. It will be seen from the figures that very much mercury was recovered in this way, and it will also be observed that the severe colitis which is so prevalent in this condition was in this case almost entirely absent, a state of affairs which we should ascribe to the method of irrigation of the large intestine used.

The autopsy revealed the following lesions (Dr. Andrews):

The *body* is that of a large, well developed and muscular white youth. Rigor mortis is marked. No markings are present on the body. The *subcutaneous fat* is present in small amount; the tissues are dry: the muscles are dark colored and very firm. The *abdomen:* The peritoneum is smooth and shining, but considerably congested, especially the visceral part. The organs are normally placed. A cecostomy has been performed and the cecum drawn up to the abdominal wall and stitched to the parietes, with a rubber tube extending into the bowel. A small amount of dark colored fluid is present in the peritoneal cavity. The *thorax:* The left pleural cavity is free of adhesions, while the right has a few on the lateral and posterior part of the lung surface. No fluid is present in either cavity. The *heart:* The pericardial sac is smooth and shining, and a few cubic centimeters of fluid is present. The heart muscle is soft and flabby. No clotted blood is present in either cavity. The valves are smooth and pliable. Tangential section shows the muscle fibers swollen and the musculature of a brick red color. The base of the aorta is smooth. The *lungs:* The left lung is voluminous, heavy, and boggy and deeply pigmented. Numerous subserous hemorrhages are scattered over the surface, especially prominent in the lower lobe. Palpation reveals no nodules in the lung substance. Section of the lower lobe shows a deeply congested and slightly edematous lung substance, with small hemorrhages scattered here and there. The upper lobe shows more edema and less congestion; considerable pigment is present. The right lung is similar in all respects to the left except that the hemorrhages are more pronounced. The bronchi are deeply congested and filled with frothy fluid. Peribronchial glands are not enlarged. The *spleen* is slightly enlarged and very soft. Quite a few adhesions bind it to the under surface of the diaphragm. Section shows an increase in the splenic pulp in which the Malpighian bodies are easily recognized. A small amount of tissue can be scraped away with the knife. The cut surface is dark red in color mottled with a few hemorrhages. The *kidneys:* The left kidney is surrounded by a small amount of fat. The organ is very soft and dark colored. The capsule strips easily, leaving a smooth surface. Section shows a deeply congested kidney substance in which the striations are easily recognized and the glomeruli appear as shining red dots. The pyramids are light colored. The pelvis shows a few petechial hemorrhages. The right kidney is similar in all respects to the left. Microscopical examination of the kidneys shows a marked tubular nephritis with congestion of the glomeruli. The *ureters* are normal. The *liver* is dark brownish red in color. The cut surface shows a swollen liver substance in which the lobulations are partially obliterated. The central part of the lobule has a dark color while the periphery is of a lighter tint. Considerable congestion is present. The *gall bladder* is normal in size and contains some dark colored syrupy bile; the ducts are free. The adrenals are normal in size and rather soft. The normal markings are clearly defined. The *pancreas* is rather soft; the lobulations are practically destroyed. It is grayish red in color with hemorrhages showing throughout. The *stomach* contains some grayish colored fluid material. The mucosa is thrown into slight folds. In the fundus considerable desquamation of epithelium has taken place exposing the deeper capillaries. The mucosa has a dark grayish color throughout, but there are no ulcers. The musculature is soft and pliable. The *intestines:* The duodenum shows numerous hemorrhages in the mucosa, mostly petechial but some are quite large. The lymphoid tissue is quite prominent. The upper part of the jejunum likewise shows hemorrhages mostly prominent on the rugi. These diminish lower down. The contents of the small intestine are fluid and consist of considerable mucus mixed with a small amount of debris. The mucosa of the large intestine is smooth. Considerable desquamation of epithelium has taken place. A few petechial hemorrhages are present. In the sigmoid and the upper part of the rectum definite ulceration has taken place. These are very small—about 3 mm. in diameter. The mucosa otherwise is quite smooth. The contents are similar to those of the small intestine. The *urinary bladder* appears quite normal. The *prostate* is normal. The throat organs were not removed, and only a portion of the *thyroid* was taken out. This portion is very firm and looks quite normal. The *brain:* The meninges are congested. The brain substance is considerably swollen, and the convolutions are flattened. No fluid is present. Section of the brain shows some congestion, otherwise it is apparently normal.

The blood findings in this case are very interesting. The patient had a polycythemia of 7,570,000. The white blood cells were 27,100, and the hemoglobin (Sahli) was 137 per cent. These figures were almost constant during the few days that the patient survived after partaking of the poison.

The organs and tissues were analyzed for mercury by the method of Ludwig,[4] and the figures are in terms of mercury bichloride (Dr. Kahn):

Tissue	$HgCl_2$ in Mgs. in 100 Gms. Tissue	$HgCl_2$ in Mgs. in Entire Organ	Wt. or Vol. of Organ or Material		Remarks
Breast bone	None				
Rib	Traces				With some muscle.
Psoas	Traces				
Pectoralis	Traces				
Skin	None				With fat.
Hair	None				
Nails	None				
Diaphragm	Traces				
Heart	1.2	4.2	345	gm.	
Lungs	1.9	29.64	1560	gm.	
Spleen	8.4	23.1	272	gm.	
Liver	19.3	303.01	1575	gm.	
Gall-bladder	Traces		18	gm.	
Bile	9.2	3.4	37	c.c.	
Kidneys	13.7	39.74	290	gm.	
Adrenals	4.2	1.05	24	gm.	
Bladder	Traces		110	gm.	No urine.
Prostate	Traces		74	gm.	
Testicles	2.1	1.2	60	gm.	
Thyroid	5.3	1.04	18	gm.	
Stomach	Traces		330	gm.	
Stomach contents	Traces		178	gm.	
Intestines	8.4	81.48	970	gm.	
Intestine contents	7.5	37.5	506	gm.	
Pancreas	2.9	2.7	95	gm.	
Brain	3.7	59.9	1620	gm.	
Pituitary	None	.....	1.2	gm.	
Blood	2.2	..	...		
Urine	203.3*	.			
Vomitus	95.3†				
Drainage I	2725.5	..	42,150	gm.	
Drainage II	82.7	..	40,400	gm.	

*Five specimens of urine were collected and analyzed. Specimen 1 contained 42.7 mg.; specimen 2, 20.4 mg.; specimen, 3 75.7 mg.; specimen 4, 53.8 mg.; specimen 5 10.9 mg.

†Three vomitus collections amounting to a total of 855 gms. were analyzed.

The largest amount of mercury was found in the irrigation fluid, a fact which would seem to indicate that some colonic washing should be resorted to in every case. Of the organs, the liver seems to contain the most of the mercury deposited.

CESAREAN SECTION

By CHAS. F. KIVLIN, M.D.,

TROY, N. Y.

CESAREAN section has long since passed the doubtful stage, and is now one of the most useful procedures that we have for dealing with the complications of labor. What its usefulness and benefits are will be unfolded as we describe the complications where cesarean section might be indicated. Judd[1] says: "In considering the best method of delivery to pursue in any atypical case of labor we should select a method which offers the least danger to the health and life of the mother and yet the greatest safety for the child." I know of no law in surgery that is quite so broad in view and which leaves so little to contradict. To those of you who differ with me in this line of surgical procedure I give you this law of Judd's as solace, that we may not go on indefinitely discussing a subject that has so many ways around, and each way having its coterie to advance the arguments of merit of his way to the detriment of the other.

As to the indications for cesarean section, as they are so well known to you, I believe it to be a waste of time to enumerate or illustrate, except possibly in a limited exception, which will be undertaken when dealing with treatment. Let me deviate from my topic for a moment to pay my respects to high forceps operation, and you can believe me that I have the most profound respect for this most dangerous and laborious operation in the domain of surgery. I speak of it to say that there never has been a high forceps operation in which cesarean section would not have been a safer procedure. I will give you verbatim what Asa B. Davis has to say concerning some of the phases of cesarean section. "In many of these women the indications are present and are positive from the beginning of labor or before. This could be appreciated, and they should be operated upon while the mother and child are yet in good condition. It should be more generally recognized that delay is dangerous, that delivery by high forceps or difficult version even in hospital surroundings and in the hands of the skillful and experienced obstetricians is among the most dangerous operations known to surgery. Even under these conditions the results are too often deplorable. Many of us know to our sorrow what the results are in the hands of the unskilled and in unfavorable surroundings. The children are apt to be born dead, or they are severely injured. The mothers who survive (there are many who do not) are made invalids for the rest of their lives in too many instances; yet prior to the birth of the child they had the right to look forward to a strong and healthful existence. A homicide occurs in a community, possibly two vicious lives are involved; one of these is already disposed of; the police, legal machinery, the press, and public opinion are at once set in motion to save or destroy the other life; time, public treasure, and legal skill are employed without stint, a knowledge of the crime is spread to the limits of the country. Yet the loss of life, the destruction of homes, permanent disability, and the sacrifice of the innocent at the time of birth is greater, we believe, than that due to homicide. It goes on quietly and is accepted without much complaint, because it always has been and now is. In the presence of appendicitis the medical and lay public are educated to such a degree that the practitioner who allows this condition to drift on unduly, and if he is not a surgeon does not seek surgical council and prompt operation when necessary, surely and justly lays himself liable to unfavorable criticism. We ask that some such condition shall be obtained regarding difficult obstetric cases. To some extent death and injury must ever be associated with childbirth. It is our duty to reduce this death rate and injury to the minimum. This calls for better obstetric teaching, a greater willingness to break away from the old methods which have been found wanting, a willingness on the part of those of us who have not been adequately trained to recognize our limitations, and to remember that time and vaginal interference, or the absence of such interference, are very important factors in determining what the outcome of a difficult labor shall be. Abdominal cesarean section is in no sense a cure-all in obstetrics. It is a very valuable agent, and its timely employment will do much to reduce the mortality and morbidity of which we complain, as is now occurring in obstetric practice."

G. M. Boyd[2] says: "The length of labor which the patient can undergo with safety will depend upon the case under study, whether she is old or young, sthenic or anemic, primaparous or multiparous, and can only be determined upon by the attendant, for some women bear labor with little constitutional disturbance and reach the second stage still in good condition, while others show signs of exhaustion early in labor. If it were possible to predetermine the method of delivery in all cases, then this expectant course of treatment would not be necessary. We do not feel that this is possible in the borderline cases. We must study each patient individually, and to maintain a low mortality great care and judgment must be exercised."

Rongy[3] says that "a close study of statistics of cesarean section of various operators compels us to assume that cases brought to the hospital with a history of a long and tedious labor, who were frequently examined or delivery by forceps attempted are supposedly infected, and therefore abdominal section should not be the operation of choice. In such cases pubiotomy becomes the operation of necessity, for it adds very little danger to the mother and saves the child. Pubiotomy is not an operation of election. Cesarean section and publitomy never compete. In cases where cesarean section is indicated pubiotomy is contraindicated, and vice versa."

Ed. P. Davis[4] says: "We are especially interested in the application of delivery by abdominal section to placenta prævia and separation of the normally implanted placenta. Placenta prævia, to my mind, is an ectopic pregnancy, quite as dangerous as tubal or other intra-abdominal pregnancy and to be treated by surgical means only. As experience increases in this direction, we find that the results are more satisfactory than by any other method of treatment.

Such cases are as much hospital cases as tubal and other extra-uterine gestations, and in hospital treatment by section, gives excellent results. Personally, I have had thirteen abdominal deliveries for placenta prævia and placental separation, with the recovery of all the mothers. All of these were suffering from the results of hemorrhage and three of them were apparently dying and greatly exsanguinated."

Barton C. Hirst[5] says: "I am not, however, arguing so much for the adoption of the extra-peritonal section in infected cases, as for its deliberate selection as the best of the operations in clean cases. I prefer the operation that I have done with success in several instances, that is the delivery of the uterus through a long abdominal incision, scrupulously padding off, the evacuation of the womb, its supravaginal amputation, a careful suture of the stump, and a suture of the parietal peritoneum around the stump well below the line of suture in it, finally, gauze drainage of the pit formed by the retraction of the stump."

Collin Foulkrod[6] says: "Those of us who have patients in hospital surroundings with few exceptions lean toward operative delivery for several reasons. The placental site is left absolutely undisturbed. The hemorrhage is therefore much less than by any method of vaginal delivery. The shock of operation is no greater, especially in primaparæ with no attempt at labor. This is a conservative expression. It is perhaps less. The child is given every chance to live. The mother, if she recovers, is left in much better physical condition. The danger of infection in unhandled cases is certainly much less by section and free drainage.

Reuben Peterson:[7] "Since the cause of eclampsia is still unknown, its treatment must of necessity be empirical. Only through the analysis of a large number of cases can the value of any particular treatment be correctly estimated. In a large series of cases of eclampsia, prompt delivery gave a maternal mortality of 15.9 per cent. as compared with a mortality of 28.9 per cent. where the delivery was long delayed. Where the uterus is emptied immediately after or very soon after the onset of the first convulsion the maternal mortality is still lower. While in a large group of cases the maternal mortaity is 5 per cent. in favor of conservative treatment and spontaneous labor in cases occurring before 1900, between 1900 and 1912, on account of better and more prompt obstetric surgery, the figures are reversed and show that the maternal mortality is lower by 4 per cent. after the radical opposed to the conservative treatment of the complication. Therefore the treatment of ante-partum eclampsia should consist in emptying the uterus as quickly as possible after the onset of the first convulsion. The operative procedure which will empty the uterus the quickest with minimum trauma and shock to the eclamptic mother and child should be selected."

The same author says again:[8] "There will be little or no discussion as to abdominal cesarean section being indicated in cases of contracted pelvis with eclampsia as a complication. Even the opponents of the oeprative treatment of eclampsia will concede that the test of labor, while indicated in borderline cases of contracted pelvis has no place in eclampsia. Medical treatment with the hope that the uterus will be emptied spontaneously presupposes that labor will be short and easy, not prolonged and difficult as is usually the case in borderline cases of contracted pelvis. Abdominal cesarean section is distinctly contraindicated in eclampsia when attempts at delivery from below have been made or when it be suspected that many vaginal examinations have been made without aseptic precautions. Under these conditions manual dilation or vaginal cesarean section are preferable procedures. Far better results would follow perforations of the child and extraction, if there be a contracted pelvis and the woman septic, than by extraction from above through an abdominal incision."

I am a believer in the lower route for cesarean section; that is by an incision between the umbilicus and the pubes and the intra-abdominal type. All that is necessary and essential should be attended to, so that the abdominal contents shall not be soiled, or soiled as little as possible. The more pains we put into execution the safer we are from any untoward sequelæ, in fact we should take the same precautions that we would if we were dealing with an infected or a pus case, and if we are dealing with a pregnant uterus with this idea in mind we will have dealt with the condition on the best surgical basis possible.

Asa B. Davis is an ardent advocate of the upper zone for his cesarean work. He is without question an authority on cesarean section and his advice should be given a great deal of logical respect, but I can not follow him because I believe that the lower route has no disadvantages that are not inherent in the upper route, and it has the additional advantage if one desires to do more than the section, as for instance the removal of the uterus, one is in the best possible position to do so; as a matter of fact it would only be a safe procedure to remove the uterus if at the time it could be determined that this organ was infected. And it also is a positive indication in many cesarean sections, which makes it a doubly hazardous operation, for in addition to the shock, there is danger from the weakened condition resulting from the absorption previous to the operation. Some operators attempt to lessen the force of the infecting agent by previously washing out the uterus. I personally cannot see any advantage in so doing, as I believe that it is impossible to wash away an infection in any place, and the attempt to wash out a pregnant uterus with its many places for foci of infection is futile, as it is utterly impossible to localize the infection. If the fact of infection can be determined before operation, then one may have recourse to one of the stock vaccines. The stimulating effect of the agent, no matter what the antibody is, upon the general system is advantageous. If the infecting agent or agents can be isolated, and there is time to make an autogenous vaccine, the result will be all the more pronounced.

A small or comparatively small incision should be made, but at the same time it should be large enough to permit of rapid and easy work. The abdomen is opened with one sweep of the knife and an incision is made in the anterior portion of the uterus from the fundus down, this incision being large enough to permit delivery of the child. The child is delivered, the cord clamped, tied, and cut, and the placenta and membranes are delivered at the same time. A dose of ergotin and pituitrin is then given. The uterus contracting, the clots are removed and the incision is closed with a continuous chromicized catgut. Starting from the lower angle the suture pierces all the coats of the uterus except the endometrium, and is continuous right up to the top. When the upper angle is reached and sewed, the

same suture is continued down but including only the serous layer so as to cover over the rough edges of the cut surface of the uterus. This suture is continued down again to the lower angle of the incision and is tied with the opposite end of the suture which has been left long for that purpose; this leaves the uterus as smooth as one could ask for, with little or no surface that might become adherent to any surrounding structures. The abdomen is then closed without any buried knots.

In the operation of cesarean section, we have three distinct methods, each having its advantages. We have the intra-abdominal route, the extraperitoneal route, and the vaginal route, each of which has its distinctive advantages which should be weighed in the individual case rather than to be bound to one distinct method. The man who will consider his case logically, deliberate upon which method will be the safer for the mother and the child, and adopt the method suitable to the particular case and the one which insures the greatest amount of certainty of a successful outcome, will have done his duty to his patient no matter what the outcome of the case may be.

Medical men in their great desire to save the mother often lose sight of the fact that the child, even though unborn, has some rights which must be respected. We should look upon this problem with a great deal of deliberation in which sentiment should play no part, either as to the family or one's own personal benefit. By saying this I do not mean that the mother has no rights, but I still persist in the belief that the child has rights which must be respected. As to the sacrifice of the mother or the child, that is a stupendous problem which every man will have to decide for himself. I have my own convictions on this subject and I trust that I shall never be placed in this most unenviable position where I should have to decide.

In the infected or suspicious cases it would be far better surgery to do an extraperitoneal cesarean section, or if not contraindicated, to do a vaginal cesarean section. Otherwise everything being equal, I would rather do an intra-abdominal section owing to the fact that it can be done so much more quickly, and also that the mortality would not be any greater. In women of forty or older who are having their first baby, the chances being that there could not be another child in any event, I believe it would be safer for the mother and child and would also shorten the period of convalescence if cesarean section were performed.

The Prodromal Rash in Measles.—H. Koch has been able to detect this rash in five out of twenty-one cases of measles closely studied from the very beginning of the incubation period. The eruption consisted of brownish-red ill-defined and fugitive macules, chiefly visible on the face. They appear coincidentally with or after the appearance of Koplik's spots.—*Zeitschrift für Kinderheilkunde.*

Medicolegal Notes.

Unlawful Granting of Degree—Doctor of Chiropractic.—A corporation styled the New England College of Chiropractic was convicted of granting a degree without authority and contrary to the Massachusetts statute. The certificate which it issued stated that "A. H. Flower, M.D., having satisfactorily completed the prescribed courses of study in the New England College of Chiropractic, passed the examinations and met all other requirements for graduation, has been declared a doctor of chiropractic." This certificate was signed by seven persons, all of whom wrote after their names the letters "D.C.," five also adding letters indicative of well-recognized degrees, such as B.S., M.D., DD.S. Flower, called as a witness by the commonwealth, after stating that the degree of Doctor of Medicine had been conferred upon him by another institution, to the question, "Have you a degree of Doctor of Chiropractic?" replied, "Yes, that is what it claims, I believe." He further testified that the New England College of Chiropractic conferred that degree on him and that at the same time the degree was conferred upon perhaps a dozen other persons, the ceremony being similar to any college or high-school graduation upon a commencement day. Officers and members of the faculty of the defendant testified in substance that the letters "D.C." stood for Doctor of Chiropractic, but that it was not a degree. It was not contended that the defendant was authorized by any special or general act of the Legislature to confer degrees. It was held that the evidence of Dr. Flower, if believed, warranted a finding by the jury that Doctor of Chiropractic was treated as a degree. The Massachusetts statute, R. L., Chap. 208, Sec. 75, provides that "whoever, without the authority of a special act of the General Court granting the power to give degrees, offers or grants degrees as a school, college, or as a private individual . . . shall be punished." The obvious purposes of the provision, the court said, was "to suppress the kind of deceit which arises from the pretence of power to grant academic degrees, and to protect the public from the evils likely to flow from that variety of misrepresentation and imposition. The earlier part of the section deals with the simulated possession of educational distinctions, including college degrees. The section as a whole is an effort to punish the issuing and holding of sham degrees from colleges and other educational institutions. It aims to insure to the people of the commonwealth freedom from deception when dealing with those who put forward professions of educational achievement such as ordinarily is accompanied by a collegiate degree from an institution authorized to grant it and to make certain that those who use such symbols have had the opportunity of being trained according to prevailing standards in some school of recognized standing, under teachers of reputation for learning (Wright vs. Lanckton, 19 Pick. (Mass.), 288, 291). The statute should be interpreted in the light of its design to effectuate its purpose so far as the words used, reasonably construed, permit of this result. Considered historically according to present practice there are three general grades of such degrees, namely, Bachelor, Master and Doctor, although by some institutions intermediate distinctions are granted. In common speech, as well as in university parlance, 'Doctor' as a prefix to a person's name signifies an academic distinction founded upon having received a degree. . . . It is not to be assumed that the statute was intended to relate only to such degrees as were in use at the time it was enacted. It is comprehensive in its terms and may include whatever properly may be described as a degree at any time. . . . The ordinary diploma of public or private schools, simply certifying to the completion of a course of study, does not contravene the statute. But when a title like 'Doctor,' commonly associated with unusual skill acquired by academic or professional study in schools or colleges, is conferred either separately or associated with other words, the statute is violated. The conferring of a title made up of the word 'Doctor' and a word relating to the healing art may be found to be the granting of a degree, within the meaning of the statute. The word 'Doctor' in connection with an unusual and high-sounding word would be quite as likely to impose upon the ignorant and credulous as the false use of the conventional Doctor of Medicine. As thus construed the word 'degree' is used with a consistent meaning throughout the section. The conviction was sustained.—Commonwealth vs. New England College of Chiropractic, Inc., Massachusetts Supreme Court, 108 N. E. 895.

THE PHYSIOLOGY OF LACTATION.

A SUBJECT of considerable theoretical as well as practical interest is that of the laws governing the secretion of milk. There has arisen within recent years a vague conception that the activity of the mammary gland is under the controlling influence of a hormone emanating from the ovaries or uterus. This idea would seem to harmonize with the observation that the mammary glands undergo a rapid growth at puberty and during pregnancy and attain their greatest functional development after delivery. The action of a hormone alone cannot account for the persistence of lactation which depends upon the act of sucking or of nursing at periodical intervals. Either of these external stimuli excites the functional activity of the mammary glands through the agency of a reflex nervous mechanism.

W. L. Gaines (*American Journal of Physiology*, August 1, 1915) has made an important contribution to this subject. He quotes the observation made by Marshall in the case of the Bohemian pygopagous twins, Rosa-Josepha, one of whom became pregnant, and in both of whom the breasts underwent development during the pregnancy and functioned following delivery. This observation would speak in favor of a hormone exciting the activity of the mammary glands, and so would the experiments of Lane-Claypon and Starling who produced a development of the mammary glands in a virgin rabbit by injecting into it extracts of rabbit fetus. On the other hand, Knoepfelmacher injected blood serum from a pregnant goat into a non-lactating goat without observing any effect upon the mammary function of the latter. Similar negative results were obtained by Gaines with the use of defibrinated blood. He found, however, that the transfusion of blood from a pregnant goat into a lactating one temporarily inhibits milk secretion. This phenomenon is apparently explained by the theory advanced by Lane-Claypon and Starling that the developing fetus passes into the maternal blood a substance which favors the growth of the mammary gland but inhibits its secretory activity. The removal of the inhibitor at delivery allows the gland to function in its natural capacity. Transfusion of blood from a heavy-milking goat into a low-milking one fails to accelerate milk secretion. Niklas, however, found that extract of placenta evokes a production of milk in virgins and mothers, and Lederer and Pribram found a greatly increased secretion of milk upon the intravenous injection of placental extract.

How can one explain the various contradictions noted in the above experiments? Gaines believes in the presence of a specific hormone which excites the remarkable growth of the mammary gland during pregnancy, but believes also that this hypothetical substance is not present in large or potent quantities in the blood of the pregnant animal or that the mammary gland of the pregnant female is for some reason more susceptible to its influence than the gland of the non-pregnant female. While admitting that the increased growth of the mammary gland is due to a hormone, Gaines finds that there is evidence that lactation is not excited by a hormone. This evidence includes the above-cited experiment with blood transfusion and the fact that one gland may cease lactating before the other.

It is found that pituitary extract has an effect on the muscular tissue of the active mammary gland, causing a constriction of the milk ducts and alveoli with a consequent expression of milk. This action of pituitrin occurs also in the case of the excised gland, being therefore independent of the blood supply, and produces a flow of milk dependent entirely upon the amount of milk present in the gland. The nonlactating gland is not sensitive to pituitary extract. A similar reflex contraction of the gland musculature is produced by nursing, milking, and the insertion of a cannula in the teat, and results in an expression of milk. Milking is a stronger excitant than the cannula; nursing is stronger than milking, and the direct action of pituitary extract in some cases is stronger than nursing. The thermal and mechanical effects of nursing provide the stimulus for the reflex that results in the expression of milk from the gland. This reflex may be inhibited by anesthesia and may be profoundly modified by the psychic state of the mother.

Other important facts revealed in the researches conducted by Gaines are that the internal capacity of the mammary gland of the goat is greater than the volume of milk drawn at one time; that the udder shrinks in volume during milking to nearly the same extent as the amount of milk withdrawn, and that practically all of the latter is present as such in the gland at the beginning of milking.

FINLAY AND THE YELLOW FEVER MOSQUITO.

DR. CHARLES JOHN FINLAY, who died at his home in Havana on August 20 at the age of 82 years, was a graduate of the Jefferson Medical College, Philadelphia, in 1855. He began practice in Havana almost immediately after graduation and soon became especially interested in the study of yellow fever, then endemic in Havana as in most of the other cities of tropical America. After many years of investigation he was led to believe that a certain species of mosquito which was shown later to be *Stegomyia calopus* was instrumental in the spread of yellow fever. His first publication of this theory was in a paper read in Spanish before the Royal Academy of Havana in 1881. In 1886 he published

another paper in the *American Journal of the Medical Sciences* in which he accurately described the yellow fever mosquito and traced its relation to epidemics of the disease. "So far as my information goes," he said, "this disease appears incapable of propagation wherever tropical mosquitos do not or are not likely to exist, ceasing to be epidemic at the same limits of temperature and altitude which are incompatible with the functional activity of those insects; while, on the other hand, it spreads readily wherever they abound. From these considerations, taken in connection with my successful attempts in producing experimental yellow fever by means of the mosquito's sting, it is to be inferred that these insects are the habitual agents of its transmission." In a paper published in the MEDICAL RECORD, May 27, 1899, before the U. S. Army Commission had taken up the work which proved the correctness of Finlay's theory beyond the possibility of denial, he thus foreshadowed the measures necessary to exterminate the disease and prevent its recurrence. "Why should not the houses in yellow fever countries be provided with mosquito-blinds, such as are used in the United States as a matter of comfort, while here it might be a question of life or death? The mosquito larvæ might be destroyed in swamps, pools, privies, sinks, street sewers, and other stagnant waters in which they are bred, by a methodical use of potassium permanganate or other such substances, in order to lessen the abundance of mosquitos; but the most essential point must be to prevent those insects from reaching yellow fever patients."

When the United States troops occupied Havana Finlay urged the claims of his theory upon the medical chiefs and finally persuaded them to appoint a commission to put it to the test. It withstood the test and was accepted as a fact by the sanitary authorities with which result the world knows. Making a practical application of this doctrine and perfecting the measures outlined by Finlay in his MEDICAL RECORD article, the genius of Gorgas converted the two notorious pestholes, Havana and Panama, into health resorts.

As we wrote some years ago, in reviewing Finlay's work, this is all ancient history, but for that very reason it is in danger of being forgotten. Even such a master of medical history as Osler forgot it in an address on the transmission of disease through the agency of blood-sucking insects, which he delivered before the London School of Tropical Medicine five years ago. In this address he omitted all mention of Finlay's work and only when he was reminded of it by a letter from Guiteras of Havana in the *Lancet* did he apparently recall the great part which this pioneer had taken in the establishment of the mosquito doctrine. No one would belittle the brilliant experimental work of Reed and his associates or the practical application of the results made by Gorgas, but in the interest of truth and as a matter of pure justice to the originator of the theory, credit and full credit should be given to Finlay. Reed himself was the last to refuse such credit and he acknowledged freely the debt which mankind owed this acute observer. In an article on "The Propagation of Yellow Fever," published in the MEDICAL RECORD, August 10, 1901, Major Reed generously said: "To Dr. C. J. Finlay of Havana must be given full credit, however, for the theory of the propagation of yellow fever by means of the mosquito, which he proposed in a paper read before the Royal Academy in that city on August 14, 1881. From that date to the present time, Finlay has made a number of valuable contributions to the origin and mode of transmission and the prevention of yellow fever."

In common with all Americans we are proud of the achievement of Reed and his associates and of Gorgas, for without their labors yellow fever would in all probability still be the curse of Havana, and the Panama Canal would be still the mosquito breeding ditch abandoned by the French twenty-five years ago; but it may be doubted whether their work would even yet have been done—it certainly would not have been done so soon—had not the way been pointed out by Charles J. Finlay.

HOUSING AND TUBERCULOSIS.

TUBERCULOSIS is initiated, developed, and spread by more than one cause, but none is more potent than that of housing. The highest death rates from the disease exist in the poorest localities and in such localities the denizens are massed together the most closely and generally the hygenic conditions are the worst.

Dr. Maxwell Williamson, medical officer of health for Edinburgh, in the presidential address delivered by him at the Edinburgh Congress of the Royal Institute of Public Health last year and published in the *British Journal of Tuberculosis*, July, 1915, pointed out that the number of cases of tuberculous disease increased in proportion as the house accommodations became limited. Further, the number of cases of the disease increased in proportion to the number of the smallest class of house. The key to the situation lies unquestionably in the housing question. If statistics prove anything, they prove absolutely that the disease originates and thrives in direct proportion to the unsatisfactory nature of the house and its surroundings, and they prove furthermore that an improvement of these conditions is invariably followed, as by the law of cause and effect, by an immediate fall in the tuberculosis rate.

Williamson summarizes as follows: (1) Pulmonary tuberculosis is a disease which in 70 or 80 per cent. of cases occurs in houses of three rooms and under; the number of cases is larger in two-roomed houses than in three; larger in houses of one room than in two; and the number of cases of tuberculous disease increases almost in direct proportion to the number of small houses, in any district or ward of a city; (2) Since the year 1882 the number of deaths from tuberculosis has shown a rapid and steady decrease, and a like statement applies to the general death rate from other forms of infectious disease; (3) The decrease has been taking place quite apart from and irrespective of any special effort to deal with the condition other than the preventive measures

which have been carried out in the ordinary march of public health administration; (4) The establishment of sanatoria and dispensaries, while useful aid in carrying on a general crusade against this form of disease, is not of itself likely to be attended by markedly beneficial results in the absence of other definite preventive measures; (5) Preventive measures center largely in the housing question, and, irrespective of cost, there is an urgent need, in the light of our present-day knowledge, of dealing more effectively than has heretofore been the case with congested areas, containing dense foci of population, and unsanitary dwellings.

HEALTH CONDITIONS IN CHINA.

The fecundity of the teeming millions of China must be marvelous to keep pace with the decimation of the population by disease, famine, and flood, for the death rate there is believed to be higher than in any other spot on the globe. This is according to the China Medical Commission of the Rockefeller Foundation, which publishes its findings in the *Bulletin of the Johns Hopkins Hospital* for June. The personnel of the commission consisted of President Judson of the University of Chicago, R. S. Green, the United States Consul at Hankow, and Dr. Francis W. Peabody of Boston.

The reasons for this fearful mortality are not far to seek. Medical practice in China is just emerging from the mists of medievalism. Anatomy and pathology are *terræ incognitæ* to the Celestial physicians owing to the fact that dissections and autopsies have been permitted there only since November 22, 1913. The knowledge of surgery among the native practitioners, as may be imagined, is extremely rudimentary. Of course, there are some Chinese medical men who have been trained in the western schools, but these are as a rule to be found in the treaty ports or in the service of the mission hospitals, which latter, by the way, are the only institutions worthy of the name of hospital in the country. The native hospitals, such as they are, are poorly managed and the members of their medical and nursing staffs are as a rule inefficient.

The most common diseases in China are smallpox, tuberculosis, leprosy, hookworm disease, and syphilis. Vaccination is almost unknown, so that a Chinaman expects to have smallpox; in fact, we might almost say he would be disappointed if he did not have it. These Orientals accept whatever destiny apportions them in the way of illnesses in the same fatalistic spirit in which they accept loss of fortune or death. It is perhaps needless to say that the armamentarium of the Chinese physician is not well stocked. Vaccines and antitoxins, serums and coal-tar products he wots not of. His remedies are decoctions from herbs, assisted by the burning of joss sticks and the simple faith of the patient. It is reported that patent medicines, largely of American manufacture, have now a large sale in China, but it is not known what color peril they are termed there.

The Central Control of State Charitable and Penal Institutions.

It has been proposed recently to establish a board of control for State institutions, including prisons, charitable institutions, and hospitals for the insane. Those who favor this scheme do so on the assumptions that (1) with many institutions in different groups there must be confusion, mismanagement, and extravagance, and (2) economy of construction and operation would be secured by combining all of these institutions into one group under one management. The arguments against this plan are well set forth in a brief submitted to the New York Constitutional Convention by the State Charities Aid Association. In order to prove their case, it is argued in this brief the proponents of the board of control must show: (1) That the present plan does not operate efficiently. (2) That it does not operate economically. (3) That further economies could be obtained without sacrificing the real efficiency of the institution. (4) That the plan proposed has been successful where it has been tried. Judged by these four tests the opponents of the scheme are of the opinion that such a drastic change is undesirable and for the following reasons: (1) The present State hospitals for the insane are operating at an extremely low rate per capita cost, lower than any other institutions of the same type on record. (2) They are operating with such extraordinary efficiency that they have established standards for practically the whole country. (3) The study of Henry C. Wright proves that the central purchasing for all institutions not only does not obtain lower prices for food, but that the prices under the plan are higher than where the central purchasing does not prevail. (4) In many of the eighteen States where the board of control has been established, it has been proved to be a device for injecting politics into the management of the institution. The standards of care in most of them have actually deteriorated, and movements are under way in many of them for a change of the system.

Fraenkel's Histological Test for Typhus Fever.

Eugen Fraenkel discovered over a year ago the important and almost unique fact that typhus fever may be diagnosticated by making serial sections of excised roseolæ and looking for small nodular inflammatory foci in the cutaneous arteries. Certain degenerative changes are also present. These finds, however, are not constant, *i.e.* are not present in all roseolæ, hence their absence cannot mean that the disease is not typhus. It is therefore necessary to make sections of a large number of spots, which consumes valuable time, so that only in very exceptional cases of possible sporadic outbreak will this diagnostic resource be indicated. At a session of the Hamburg Medical Society last winter Fahr related the case of a patient who was seized with a severe angina. On the sixth day a roseola appeared and one day later the patient died. Eight nodules, six of which were excised postmortem, were subjected to serial section. In one of these the Fraenkel finds were present. In discussion Rumpel stated that typhus not rarely begins with severe angina, a fact not to be found in textbooks. Whenever a subject arrives from a typhus region with the picture of septic angina one should always, it was said, suspect typhus.

The Comparative Hemostatic Power of Various Tissues.

Within recent years considerable practical use has been made of the discovery that bits of living tissue when applied as grafts to accidental or surgical wounds, particularly of the parenchymatous organs, act as efficient hemostatics. The tissues most commonly employed for this purpose are subcutaneous or subperitoneal connective tissue, aponeurotic fascia, muscle, and omental tissue. Luigi Torraca contributes to *Lo Sperimentale*, July 14, 1915, the results of an important study with reference to the comparative hemostatic power in vitro of the above tissues. He finds that the coagulating action of these tissues varies among them and even in the same tissue according to the region from which this tissue is derived. The hemostatic power is greatest in omental tissue and least in aponeurotic tissue, while muscle and adipose tissue occupy an intermediate place. The differences, however, are so slight as to be of little value from a practical viewpoint. For surgical purposes all the tissues usually employed for their hemostatic virtue may be regarded as of equal power in this respect.

News of the Week.

Death Rate of New York.—During the week ending August 14 the number of deaths in New York City was 1,322, giving a death rate of 11.88, as compared with 13.30 for the corresponding week of last year. The death rate for the first thirty-three weeks of 1915 was 13.75 as compared with 14.19 for the corresponding period of 1914.

Abandonment of Fumigation.—In December of last year the Health Department of this city discontinued the practice of fumigation of premises after the occurrence of a case of infectious disease in all the boroughs except Brooklyn, where it was maintained for the purpose of control. As to the results of the experiment, the Board reports that in the Borough of Manhattan, 193 later cases occurred among 3,451 primary cases of diphtheria. Of these, 171, or 4.9 per cent., would not have been affected by fumigation, and 22, or 0.6 per cent., might have been so affected. In Brooklyn, where fumigation was performed, there were 138 later cases among 2,907 original cases. Of these, 110, or 3.8, would not have been affected by fumigation, and 28, or 0.9 per cent., might have been so affected. In other words, there were half again as many later cases in Brooklyn, where fumigation was done, as in Manhattan, where it was not done. Fumigation will now be abandoned in Brooklyn as well as in the other boroughs and in place of it insistance will be laid on thorough cleaning, opening up to fresh air and sunshine, and renovation of the premises by painting, papering, and kalsomining.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, treasurer, 7048 Jenkins Arcade Building, Pittsburgh, Pa., reports the receipt of the following contributions for the week ending August 21, 1915:

Dr. G. N. Kreider, Springfield, Ill.	$5.00
Dr. Hugh A. Cuthbertson, Chicago, Ill.	10.00
Total	$15.00
Total receipts	$7,804.84
Total disbursements	7,310.04
Balance	$494 80

Proposed Abolition of the Death Penalty.—The following amendment has been offered to a proposal before the New York State Constitutional Convention for the total abolition of the death penalty: "On a conviction for a crime now punishable by death, the jury may, by its verdict, impose either the death penalty or life imprisonment and in the latter event no pardon or commutation shall be granted unless the innocence of the prisoner convicted is legally established." It is stated that twenty-seven States now have this method of reaching the crime of murder, while fourteen States have the straight death penalty, and in seven States the death penalty has been abolished altogether.

Physician to the King a Spy.—According to a report from Sofia, Dr. Gruetzel, who had been personal physician to King Ferdinand of Bulgaria for twelve years, has been found to be acting as a spy for the German government and has accordingly been dismissed as a traitor.

The War's Victims.—A despatch to *The Sun* gives the following official list of killed, wounded, and prisoners as submitted to the French Senate:

	Killed	Wounded	Prisoners	Totals
Allies	1,739,000	2,589,000	1,135,000	5,463,000
Teutons	3,350,000	3,885,000	1,795,000	9,030,000
Totals	5,089,000	6,474,000	2,930,000	14,493,000

The figures distribute the number of killed as follows: French, 460,000; English, 180,000; Russians, 1,250,000; Germans, 1,630,000; Austrians, 1,610,000; Turks, 100,000; Belgians, 49,000.

The Sun discredits the figures as excessive.

The Typhus Germ.—The *Staats-Zeitung* of this city recently announced the discovery of the germ of typhus fever by Dr. Friedrich Proeschel and said that the announcement of this discovery had been very warmly received in Frankfort, Berlin, and Vienna, and Dr. Proeschel had been urged to join the medical staff of the German army. Until this news was published we had supposed the typhus germ was discovered by an American physician, Dr. Plotz of Mt. Sinai Hospital, New York.

Award of a Medal to Surgeon-General Blue.—The trustees of the *American Medicine* gold medal award have unanimously selected Surgeon-General Rupert Blue as the recipient of this token, which is given each year to the American physician who is adjudged to have done most for humanity in the domain of medicine during the preceding twelve months.

Dr. Alexis Carrel of the Rockefeller Institute, New York, who is at present in the medical service of the French government and in charge of a hospital for wounded soldiers, is to receive the next promotion to the rank of officer of the Legion of Honor.

Dr. Elisha H. Cahoon, assistant physician at the Providence, R. I., State Hospital for the Insane, has been appointed physician, in association with Dr. E. E. Southard, to the Massachusetts State Hospital at Boston. Before going to Providence Dr. Cahoon was assistant physician at the Iowa State Hospital, and previous to that assistant superintendent in one of the Colorado State Hospitals.

Dr. A. S. Spoor of Big Rapids has been appointed State bacteriologist in charge of the laboratory at Lansing, Mich.

Dr. Charles E. Phipps of Muncie, Ill., has been appointed assistant surgeon to the National Soldiers' Home at Milwaukee.

Dr. James E. Drake of Lamont has been appointed health officer of the public schools of Spokane, Wash., by the board of education of that city. He will have two trained nurses as his assistants, but will be the sole physician on the work.

Naval Medical Reserve Corps.—At the prelimi-

nary examination beginning July 6, 1915, held in various cities of the United States, for examination of candidates for appointment as assistant surgeons in the Medical Reserve Corps of the Navy with a view to subsequent examination and appointment in the Medical Corps of the Navy, after a course at the Naval Medical School, the following candidates were found physically and professionally qualified: Drs. Virgil Hope Carson, Elphege Alfred Gendreau, Francis DeArmond Gibbs, John Harper, Forrest Martin Harrison, Richard Hagan Miller, John Paul Owen, John Floyd Pruett, William Jehiel Rogers, George Patrick Shields, George Washington Taylor, Russell John Trout, George Boyd Tyler, Walter Alfred Vogelsang, Charles Henry Weber, Grover Cleveland Wilson.

Civil Service Examinations.—The New York State Civil Service Commission announces examinations to be held on September 18 to fill the position of laboratory assistant in bacteriology and of assistant medical officer at the quarantine station of the port of New York. The salary attached to the first named position is from $720 to $1,200 per annum, and men and women, citizens and non-citizens, residents and non-residents are eligible. Only candidates who have satisfactorily completed a systematic course in bacteriology and have also had not less than eight months' practical experience in laboratory work will be accepted. Candidates will be examined on the technical procedures used in the study of the pathogenic bacteria of infectious disease, immunity, and the standard methods used in the examination of milk, water, sewage, air, and soil. The second position, which carries a salary of $1,500 and is open to men only, is in the Detention and Hospital Service of the Quarantine Station and involves residence and service at either of the quarantine islands in Lower New York Bay. It requires a knowledge of cholera, plague, yellow fever, smallpox, leprosy, epidemic cerebrospinal meningitis, and typhus fever. Examination is open only to licensed medical practitioners of the State of New York who are certified graduate internes after a course of at least fifteen months in a general hospital.

Twilight Sleep.—A motion picture exhibition was given to a large audience, the guests of the *Medical Review of Reviews*, at the Candler Theater, New York, on the afternoon of August 25. Before the pictures were shown the method was explained to the audience, composed of sociologists, public health workers, and physicians, in a lecture by Dr. Schlössingk of the Kroenig-Gauss Klinik of Freiburg.

The Michigan State Medical Society will hold its fiftieth annual meeting at Grand Rapids on August 31 and September 1 and 2, under the presidency of Dr. Reuben Peterson of Ann Arbor. The secretary is Dr. F. C. Warnshuis who is also president of the Kent County Medical Society.

The Panama-Pacific Dental Congress is announced to meet in San Francisco from August 30 to September 9, under the presidency of Dr. Frank L. Platt of that city.

The National Medical Association, a society of colored physicians, dentists, and pharmacists, held its seventeenth annual session in Chicago on August 24-26, under the presidency of Dr. F. S. Hargrave of Wilson, N. C. The secretary of the Association is Dr. W. G. Alexander of Orange, N. J.

American Medical Editors' Association.—The annual meeting of this Association will be held at the McAlpin Hotel, New York City on October 18 and 19, under the presidency of H. Edwin Lewis, M.D., editor of *American Medicine*. An interesting program has been prepared upon important subjects of interest to every medical editor in this country. The annual banquet will be held at the McAlpin Hotel on the evening of October 19.

Health Conference in Rochester, N. Y.—The Bulletin of the New York State Department of Health says that plans are being actively carried forward for the Health Conference at Rochester in September which promises to be the most notable public health convention ever held in the United States. The following general program has already been outlined by the cooperating organizations, the American Public Health Association, the New York State Department of Health, the New York State Sanitary Officers' Association, and the Rochester Public Health Association.

Monday, September 6, 8 P. M.—Opening meeting for Health Officers of New York State, Commissioner Hermann M. Biggs, presiding. Address of welcome, G. W. Goler, Health Commissioner of Rochester. Address by Surgeon-General W. C. Gorgas, U. S. Army.

Tuesday, September 7, 10 A. M.—Sectional meetings of the Health Officers of the State of New York, under the chairmanship of the Sanitary Supervisors. 8 P. M.—Opening meeting of the American Public Health Association, under the presidency of Prof. William T. Sedgwick. Addresses by Governor Charles S. Whitman and others.

Wednesday, Thursday, and Friday, September 8-10.—Meetings of the American Public Health Association. Special sessions will be arranged for the Health Officers of New York State dealing with Rural Hygiene, Milk, Control of Communicable Diseases, Public Health Education, and Diseases of Adult Life.

Wednesday, September 8, 4 P. M.—Business meeting of the New York Sanitary Officers' Association. 8 P. M.—Public meeting under the auspices of the New York State Sanitary Officers' Association, Dr. Montgomery E. Leary, presiding. Addresses by Secretary W. C. Redfield, Department of Commerce, Dr. Norman Bridge, and others.

On the mornings of Tuesday, Wednesday, and Thursday, between 9 and 10 A. M., there will be held a series of clinics on tuberculosis and infant hygiene and of demonstrations of public health laboratory methods, open to the health officers of New York State, and the members of the American Public Health Association. The tuberculosis clinics will be conducted by Drs. S. A. Knopf, Lawrason Brown, A. H. Garvin, and others, the infant hygiene clinics by Dr. H. L. K. Shaw, and the laboratory demonstrations by Dr. A. B. Wadsworth.

Obituary Notes.—Dr. EDMUND L. WOODS of Janesville, Wis., who was one of the victims of the massacre of non-combatants on the *Arabic* on August 19, was a native of England and returned there last spring to work in the English field hospitals. He came to this country when a child and was graduated from the Medical College of Indiana, Indianapolis, in 1882. Dr. Woods was a member of the American Medical Association, the State Medical Society of Wisconsin, and the Rock County Medical Society. He was a naturalized citizen of the United States, and was 61 years of age.

Dr. SAMUEL H. WOLLERTON of New York City, died at the home of his brother at Scranton, Pa., on July 27, at the age of 55 years. He was grad-

uated from the medical department of the University of Pennsylvania in the class of 1880.

Dr. JOHN BACON died at Philadelphia on August 2 at the age of 50 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1889. He served as intern in the Hospital of the University and later as physician to the Eastern Penitentiary. He was a Fellow of the College of Physicians of Philadelphia, a member of the Philadelphia County Medical Society, and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. JEANNE DE LA MONTAGNIE LOZIER of New York, a graduate of the New York Medical College and Hospital for Women, and for some years professor of physiology and chemistry in this institution, died at her summer home in New Brighton, Staten Island, on August 6, aged 74 years.

Dr. CLARA EMMA WATSON formerly of Norwood, Ohio, a graduate of the Eclectic Medical College of the City of New York in 1895, died at her residence in Brooklyn, N. Y., on July 31, aged 54 years.

Dr. ALBERT MERRELL of Wilmington, Del., a graduate of the American Medical College of St. Louis, Mo., in 1875, formerly of St. Louis, and for twenty-four years a member of the Missouri State Board of Health, deeply interested in public health questions, and one of the organizers of the St. Louis Pure Milk Commission, died at his home on July 21, aged 72 years.

Dr. JOSIAH JONES of Tacoma, Wash., a graduate of the Rush Medical College, Chicago, in 1890, and a member of the Washington State Medical Association, the Pierce County Medical Society, the Pacific Coast Oto-Ophthalmological Society, and the Puget Sound Academy of Ophthalmology and Oto-Laryngology, was killed on July 5, when an automobile which he was driving skidded on a wet pavement and turned over, crushing the physician beneath it.

Dr. RELL M. WOODWARD, surgeon in the United States Public Health Service, and for many years in charge of the Marine Hospital at San Francisco, a graduate of the Miami Medical College, Cincinnati, in 1887, and a member of the Public Health Service since that time, on duty in Rotterdam during the cholera epidemic of 1893, at different times in charge of hospitals at Boston, Baltimore, and Chicago, and a member of the American Medical Association, died at St. Mary's Hospital, Rochester, Minn., following an operation, on July 16, aged 53 years.

Dr. SIMEON DOSSON TAYLOR of Beaver Dam, Ky., a graduate of Vanderbilt University, Medical Department, Nashville, Tenn., in 1887, and a member of the Kentucky State Medical Association, and the Ohio County Medical Society, died at his home from typhoid fever, after a short illness, on August 2, aged 53 years.

Dr. THOMAS LAWRENCE MCDERMOTT of Louisville, Ky., a graduate of the Bellevue Hospital Medical College, New York, in 1866, attending physician at SS. Mary and Elizabeth Hospital, a member of the Kentucky State Medical Association and the Jefferson County Medical Society, former health officer of Louisville, and a member of the Board of Safety, died at St. Joseph's Infirmary, Louisville, from cancer of the throat, after a long illness, on August 1, aged 72 years.

Dr. JOHN KENDRICK GILMORE died of angina pectoris at Renovo, Pa., on August 5, at the age of 56 years. He was graduated from the Detroit College of Medicine and Surgery in the class of 1892.

Dr. JAMES L. WHEATON of Pawtucket, R. I., a graduate of the Harvard University Medical School, Boston, in 1846, died at his home on August 12, aged 92 years.

Dr. PHILIP COFFMAN PALMER of Kansas City, Mo., a graduate of the Rush Medical College, Chicago, in 1884, died suddenly, from heart disease, on August 1, aged 63 years.

Obituary.

PAUL EHRLICH, M.D.,

FRANKFORT, GERMANY.

Dr. PAUL EHRLICH, director of the Institute of Experimental Therapeutics at Frankfort, Germany, the originator of the side-chain theory, the inventor or salvarsan, and one of the foremost medical scientists of the world, died suddenly from heart disease at Bad Homburg on August 20, aged 61 years. Professor Ehrlich was born at Strehlen, in Silesia, March 14, 1854, and was educated at the Universities of Breslau, Strassburg, Leipsic, and Freiburg. He was an ardent student of chemistry and most of his discoveries and contributions to medical science were in the line of the application of chemical principles to animal pathology. His side-chain theory was one result and his development of chemotherapy culminating in the invention of salvarsan was another. In 1908 he divided the Nobel Prize in medicine with Metchnikoff, and in 1910 he announced his discovery of salvarsan, which at the time was hailed as one of the most important advances ever made in medicine. In 1913 he was introduced by Sir Malcolm Morris to the International Medical Congress in London, before which he delivered an address on pathology, as "the greatest exponent of modern pathology in the civilized world" and received an ovation from the delegates. The Decoration of the Second Class of the Red Eagle was conferred on him by Emperor William in 1914, and in the same year he was awarded the Cameron Prize by the University of Edinburgh.

CARLOS JUAN FINLAY, M.D.,

HAVANA, CUBA.

Dr. CARLOS JUAN FINLAY of Havana, the discoverer of the agency of the Stegomyia mosquito in the spread of yellow fever, died at his home on August 20, aged 82 years. Dr. Finlay was of Scotch descent, born at Puerto Principe, Cuba, December 3, 1833. He received his medical education in the United States, being graduated from the Jefferson Medical College, Philadelphia, in 1855. His researches into the etiology of yellow fever began soon after his return to his native country. In 1881 he was delegate from Cuba to the International Sanitary Conference in Washington. From 1902 to 1908 he served as chief sanitary officer of Cuba, and since 1909 had been honorary president of the Junta Nacional de Sanidad y Beneficencia. He was a member of the Havana Academy of Sciences, the College of Physicians of Philadelphia, and the American Public Health Association, an honorary member of the American Society of Tropical Medicine, and the Société de Médecine Tropicale of Paris, a corresponding member of the Académie de Médecine of France, and a fellow of the Society of Tropical Medicine and Hygiene of England.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ANTISEPTICS—REPORT TO THE RESEARCH COMMITTEE —MALACHITE-GREEN—HYPOCHLORIC COMPOUNDS —EUPAD, EUSOL, ETC.—THE WAR.

London, August 6, 1915.

Drs. P. Fildes and L. W. Rajchman, workers in the London Hospital Laboratory, have proposed a new antiseptic mixture which they think will be specially useful in gunshot wounds. They some time ago, in collaboration with Surgeon-General Cheatle, made a preliminary report to the Medical Research Committee and their work seems deserving of attention, although their conclusions differ from those of some observers who may well take them into serious consideration. Asepticism has for so long held sway in our literature and conversation that antiseptics have largely disappeared from civil practice and on the outbreak of war surgeons meeting with septic wounds turned to the remedies with which they had had experience, such as iodine, thinking it would kill the bacteria, and mild antiseptic lotions, which in actual contact with germs might have some effect, this condition implying that it could only be skin deep. But in gunshot wounds the infection as a rule is carried beyond the surface. Confronted by a deep focus of suppuration the surgeon knows the first essential is a means of drainage, so he opens the focus freely as otherwise nothing will save the patient. This done accessory measures may be employed, and among them antiseptics, for in the majority of cases the infection is superficial. However complex the recesses of the wound the bacteria are mostly confined to the surface.

It has been the practice of many to use mixtures of different antiseptics, but these investigators found this plan undesirable, at any rate with mercury and carbolic, for the compound was less potent than mercury perchloride alone. They were led to try the effect of aniline dyes and after some experiments selected malachite-green as a strong antiseptic which killed *Staphylococcus aureus* in serum, 1 in 2000, while with spores it is more potent, killing *B. subtilis* spores in a dilution of 1 to 5000. This dye does not diminish the effect of corrosive sublimate. Coloring the skin is no disadvantage. The solvent employed was 80 per cent. spirit; the small quantity of water in this seemed greatly to increase the effect. The best mode of using is spraying. The actual quantity thus used is small and evenly distributed.

The malachite-green is not very toxic and it can be used stronger, but 1 per cent. was found sufficient. It was mixed with corrosive sublimate, at first 1 in 500 dilution; eventually 1 in 200, but of course is not to be applied to mucous membrane in any case. The authors of the report made two separate solutions in spirit (80 per cent.) of 1.0 gram of pure malachite-green in one; and 1 gram corrosive sublimate in the other to 100 c.c. of the solvent. These two solutions they mixed in equal parts at the time of using as they found if kept ready mixed a compound of the two substances crystallizes out in a few days. The combined solutions they spray on to the wound, which at once turns green, but the color is discharged after a few hours from healthy tissues, but is retained by sloughs and dead bone.

Much of the malachite-green in the market is very impure. What are called "pure samples" often contain impurities soluble in alcohol. The spraying must be thorough, with a good instrument held as far as possible from the wound which it must completely cover, and extend over a wide area of surrounding skin.

Another investigation on this subject way well be considered in connection with the foregoing. It has been made by Drs. Lorain Smith, Murray Drennan, Theodore Rettie, and William Campbell, and was undertaken to find an antiseptic which could be applied as a first dressing in the field to prevent sepsis, but it included incidentally other points. At the outset they directed attention to the hypochlorites which have long been recognized as the most potent disinfectants, the best known, chloride of lime or bleaching powder being largely employed in the arts and by sanitary authorities.

But hypochlorites do not keep well in solution and there are other drawbacks to their use in surgical practice. These salts, too, are less powerful than the free acid, so the four pathologists engaged in this research devised a method of using it in its gaseous state or dissolved in water. The method is to prepare the gas by the action of boric acid on bleaching powder in the presence of a small quantity of water. The solution is obtained in the same way, but using a large quantity of water. A powder composed of finely ground bleaching powder and boric acid powder also finely ground (equal weights) they call eupad and the solution of the acid they term eusol. A strength of 0.5 per cent. of acid they found most satisfactory. It can be safely applied to open wounds. Many laboratory experiments are related both with the acid and its salts and go to show that bleaching powder retains its reputation as the chief of disinfectants. In other series of experiments the potency of the acid and its salts was compared with various antiseptics, showing them to be the most effective.

Chemical observations have also been made in more than one hundred cases treated with the antiseptic in one form or another. They give promise that the laboratory results will be realized in practice.

The conclusions reached by the investigators confirm the view generally entertained that hypochlorous acid is the most powerful antiseptic known and that practical methods of using it have been devised. Further they say—it can be used as gas or solution. The advantage of gas is that it will penetrate and act at a distance. Both gas and solution while extremely potent against organisms and their spores, cause little or no harm to the tissues. Fetor is rapidly eliminated. If pain and irritation occur they can easily be controlled by reducing the concentration of the antiseptic. A flow of lymph from the wound is reduced. The effect is purely local; decomposition products devoid of toxicity, so no danger from absorption. For field use the advantages are (*a*) it can be used as a dry powder, so obviates difficulty of procuring water; (*b*) can be introduced into the gauge pad of the first field dressing; (*c*) where water is available the same powder can be made up as a lotion for general use. The constituents of the powder are inexpensive, easily procured, and the preparation of the antiseptic extremely simple.

A committee of fifteen members of the British Medical Association with power to add others has been appointed to consider various aspects of the

war in relation to men and to act in the interests of those serving now and of those who may offer their services in the future.

7. **Tuberculosis Associations as Health Educators.**—M. M. Davis states that the very success of the antituberculosis campaign has brought with it two dangers: First, that of over-specialization, a danger which creates, as it were, a vested interest in preventing tuberculosis, and fails to see its intimate relationships with other phases of militant public health work. The second danger is the popular fear of tuberculosis, which has been so developed as a by-product of the educational campaign that it acts in many ways as a handicap upon existing work and upon further progress. Anti-tuberculosis associations in their capacity as educators must devote themselves to informing the public that while it is well to fear tuberculosis, it is not well to fear it in the wrong way. The dread of the disease should be based on information as to how the infection is most likely to be carried. They must understand that the way in which infection is usually carried renders a tuberculosis hospital harmless, either to life (or property values) in its vicinity; but that, on the other hand, an active consumptive in the midst of his home and family is dangerous to wife, neighbors, and, above all, to the children. As health educators, anti-tuberculosis associations must teach the public to stop the waste of money and effort which arises from the discharge of sanatorium patients without adequate supervision after they leave the institution. As health educators tuberculosis associations must educate both the doctors and the public toward the early diagnosis of the disease. The author advocates as a measure of economy the co-ordination of the activities of the various public health movements, none of which will profit more thereby than the anti-tuberculosis movement.

1. **Treatment of Obesity.** — Beverley Robinson has found two remedies of value in reducing flesh. One is the phosphate of sodium, given at bed time in teaspoonful doses in a little water. The other is the solution of the hypophosphites of calcium and sodium, ten grains to the dose, given at meal time, as a general tonic to the nervous system. It does in some unexplained way, tend to reduce the amount of fat in the individual. The phosphate of sodium is particularly indicated in persons whose livers are engorged by numerous dinners and indulgence in rich wines and pure alcoholic drinks. The author advocates also the use, after meals and at bed time, of the Bulgarian culture in tablet form, to be taken two at a dose. In many instances of obesity the increase of fat is due in a degree, more or less important, to fermentative processes going on constantly in the bowels and from which poisonous results are constantly derived.

2. **Cardiovascular Disease.** — E. E. Cornwall states that dyspnea is an important and often an early symptom. It may be slight, brought on only by unusual exertion, or it may be severe; it may even occur when the patient is at rest, and it may occur in paroxysms. Abnormal sensations in the precordium may appear among the early or late symptoms, and may vary from a slight sense of oppression or uneasiness to a dull pain with radiation to the shoulders or arms, or angina pectoris. Some of these sensations, in their milder forms, may be present without necessarily indicating lesions of cardiovascular disease. Headaches, dizziness, vertigo, and head noises are common symptoms, as are also mental disturbances, particularly insomnia, irritability, changes in disposition, and dementia. Neurasthenic symptoms are frequently met with in the early stages of the disease. A tottering gait, a trembling hand, transient attacks of aphasia, or a paralytic stroke, point to changes in the cerebral arteries. The diagnosis of cardiovascular disease ultimately depends on the physical signs, although it may be suggested by symptoms and syndromes and by heredity and previous history. These physical signs, like the symptoms, may be shy in manifesting themselves, but usually before the disease has advanced very far some of them can be found if diligently sought for. A persistent rise in blood pressure is suggestive, particularly of the renal type of the disease. Impurity or roughening or enfeeblement or equivalence of the heart sounds or the appearance of a systolic murmur over the aortic cartilage, with or without much increase in the blood pressure, suggest myocardial degeneration or sclerotic changes in the aorta or its valves. Some of the earliest signs of the disease may be discovered in the ophthalmoscopic picture of the retina. Increase in the quantity of the urine and diminution in the quantity of urea excreted, with or without the appearance of albumin or casts, is also a significant sign. The later signs of the disease are usually plain, although not infrequently it happens that a cardiovascular accident suddenly reveals the unsuspected condition.

6. **Tests of Renal Permeability.**—R. H. Greene draws the following conclusions: If one kidney is diseased and the other sound, through ureteral catheterization phloridzin will demonstrate which of the two kidneys is in the best condition. Second, it is the most practical test for the general practitioner, without ureteral catheterization, at present at his command, being more accurate in its findings than the phthalein test and less complicated than the nitrogen test. Third, the delay of appearance of sugar in the urine following its administration will almost invariably indicate either a diseased condition of the kidney, or less frequently some abnormal condition of the system. Fourth, delayed appearance of sugar following the use of phloridzin, furnishes a marked indication of some diseased systemic condition and is a strong indication for farther investigation. This paper is an effort not only to repopularize the phloridzin test as far as we have found it available, but also to stimulate research along this

line and thus aid the finding of the ideal practical method.

10. Newer Therapeutics in Otology.—S. Moskowitz believes that vaccines should be used in every case of ear infection from furunculosis to mastoiditis as early as possible. If a case has been treated by a stock vaccine, and no change has been observed for the better, the autogenous should be used at once. All other modes of recognized aural treatment should be instituted, and kept up during the vaccine therapeutics. In very severe cases where there is no improvement and the disease is progressive, and it is not advisable to wait, the appropriate operation should be performed. Errors in vaccine therapy may occur from two sources: (1) Using the wrong vaccine, or poor and faulty smear taken for the production of the autogenous vaccine. (2) Using too little vaccine, and not persisting for a few injections, with such regularity as the case may need. In very severe cases the author has used daily injections until signs of improvement were manifest, and then every other day, continuing twice weekly until discharge of case. My results have been excellent, even in some very neglected cases, in which anatomical destruction was not too great.

5. Relation of Animal to Human Sporotrichosis.—K. F. Meyer notes that spontaneous sporotrichosis of domesticated animals, particularly horses, is very common in certain parts of the United States. Extensive bacteriological and serological experiments have proved the identity of the causative organisms in human and animal sporotrichosis. The pathogenicity for human beings was observed in an accidental laboratory infection. The geographical distribution of equine sporotrichosis, which is apparently closely connected with certain telluric and climatic conditions, covers, in two states, the same territories from which numerous cases of human infection have been reported in the last five years. In Pennsylvania, equine sporotrichosis—as so-called "epizeotic lymphangitis"—has been noted in as many as 150 cases annually. Only two human cases are on record in that state. A careful study of one case suggested at first a contact infection with a sporotrichortic horse, but this assumption could not be proved conclusively. The evidence collected does not support the theory that human sporotrichosis is very frequently transmitted from horse to man in the United States. The cases of Hyde and Davis, Sutton and others are discussed from this point of view, and compared with the cases reported by Gougerot, Carougeau, Lutz and Splendore, and Rouslacroix. The absence of sporotrichosis among veterinarians and farmers in Pennsylvania—where equine sporotrichosis is so exceedingly common, calling forth undoubtedly close contact with infectious material—demonstrates that sporotrichotic infections in man are established by this channel of contact in rare instances only.

14. Hospital Observation in Alleged Mental Disease.—H. R. Stedman concludes that hospital observation is a measure of proved value in doubtful cases of mental disease and defect in both criminals and noncriminals, and is growing in favor. It affords the opportunity for constant observation and ample time for thorough examination under the best conditions of trained hospital psychiatrists. It is of especial value in capital cases, in cases with concealed delusions and in the detection of maligners. It tends to make less frequent the plea of insanity as a defense for crime, and to lessen disrespect for expert medical opinion. In many noncriminal cases it saves persons from hasty and ill-considered commitment as insane. There appears to be every reason why the many States which are without this valuable provision should adopt it, particularly as it has been long in successful operation in some form in six States and in Germany, and has the endorsement of foremost jurists and alienists.

2. Malignant Aortitis.—H. D. Rolleston reports the case of a man aged 34 years who was admitted to the hospital with fever gastric irritability, and vomiting. His illness dated from an attack of influenza one month before. He died nearly three months after admission to the hospital. The most probable diagnosis during life was subacute bacterial endocarditis; but the negative result of the blood culture, which, however, was only carried out once, the absence of splenic enlargement and of obvious infarctions, and to some extent the stationary condition of the cardiac signs, were recognized as militating against this view. The constant albuminuria was, perhaps, not given its proper value as evidence in favor of malignant endocarditis, and the spleen, though obviously enlarged at the necropsy, was never felt during life. An alternative diagnosis—latent carcinoma of the cardiac end of the stomach—was suggested by the association of gastric symptoms, grave secondary anemia, and fever, while the occurrence of thrombosis was quite compatible with this interpretation. Trousseau, who insisted on the association of thrombosis and gastric carcinoma, exemplified this in his last illness, and remarkable instances of multiple thrombosis in this disease have been described by Osler and McCrae. Pernicious anemia was excluded by the blood count, and especially by the presence of leucocytosis. The morbid lesion present in this case, which

appears to be analogous to malignant or subacute bacterial endocarditis, being situated in the arch of the aorta instead of on the endocardium, was not proved to be infective, as the only blood culture made was negative and no bacteria were seen in a smear from the pus found just outside the aortic lesion. Libman has shown that bacteria-free periods occur in subacute bacterial endocarditis; but as the blood culture was made on April 4, when the disease as shown by the temperature chart was active, it would hardly be justifiable to explain the failure to obtain a positive result by the hypothesis that this was an analogous bacteria-free period in a case of infective aortitis. Libman, however, points out that in cases of subacute bacterial endocarditis with high temperatures and with very well marked oscillations blood cultures are sometimes negative, although bacteria are present in enormous numbers in the vegetations in the heart; and presumably this might hold good in the analogous condition of infective aortitis. Although the view that the case was one of infective aortitis is attractive, it is safer to describe it as one of malignant aortitis.

6. Relation of Ventricular Fibrillation to Clinical Chloroform Syncope. — E. H. Embley concludes that syncope from cardiovascular inhibition in dogs occurs only in the period of induction. This is the period of incidence of clinical chloroform syncope. That of ventricular fibrillation in the cat may occur at any time in re-induction during a prolonged course of administration. Cardio-vascular syncope from chloroform in the dog is frequently recovered from by artificial respiration, either alone or in conjunction with heart massage. This coincides with the recoveries from syncope in clinical instances. In the author's experience established syncope from ventricular fibrillation in cats is not recovered from. If it is ever recovered from it must be very rare. The control of the cardiac rhythm in the dog is markedly vagal and approximates in this respect to that of the human being. In the cat, on the other hand, marked vagal control is not characteristic, and such control is readily inhibited. A heart under vagus control is not prone to ventricular fibrillation, hence, like that of the dog, the human heart should not be liable to ventricular fibrillation. Reflex syncope from cardiovascular inhibition in dogs under chloroform anesthesia occurs as readily as that in cats from ventricular fibrillation. Syncopal states occur clinically either reflexly or from overdose, in which the heart does not stop, but the rate becomes very slow. This resembles similar states occurring in the chloroformed dog which are promptly corrected by vagotomy. This statement appears to the author to show a considerable balance of probability in favor of cardiovascular inhibition as being the cause of clinical chloroform syncope. In view of this, one must regard the protest made by Levy against the exercise of care to prevent overdosage as unwarranted by the data and as a dangerous teaching.

2. Anoci-association in Medical Practice. — F. M. Rowland believes that one may glean for one's everyday dealing with the treatment of illness some very useful truths from the theory of anoci-association as understood to mean the exclusion of all nocuous and harmful associations; and to this end the author pleads for the more systematic study and consideration of our patients' individual outlook upon life, not so much when in their normal health as when they are lying on a bed of sickness. At such times the subconscious mind is more in the ascendant, altered in its sensitiveness, and likely the more eaily to become the recipient of suggestions than in health, the mental attitude of a patient being so affected by an illness as to be altogether different from the mental attitude of the same person when in normal health. It is only by an experience, not otherwise obtainable than by years of intimate observation of the varying temperaments and idiosyncrasies of our patients, that one can judge even in the smallest degree of the lines of thought they will adopt at any given juncture, and by our knowledge so gained that one shall be enabled to some extent possibly to assist in influencing the course of their disease by the exclusion of all adverse subconscious tendencies, and by the furtherance of beneficial influences operating towards a cure.

4. Gunshot Wounds of Small Intestine.—O. Richards points out that death in uncomplicated cases of gunshot wounds of the small intestine is not usually due to escape of feces and general peritonitis, but to a progressive intestinal paralysis and distention spreading upwards from the injured coil. 2. Operation in such a case should include the resection of the injured portion together with as much bowel above it as would otherwise remain in a condition of paralysis. 3. If this be done sufficiently early there is a prospect of saving a fair proportion of cases. These conclusions are based on a small number of cases, those of which notes are given. Wider experience or the experience of other surgeons may perhaps modify or contradict them; meanwhile their practical importance at this time justifies their publication.

Progress in Electrotherapy in 1914.—Tobias sums up the advances in this department of therapeutics under d'Arsonvalisation, diathermy and Bergonisation. In regard to the former the Germans have always been skeptical of the results claimed for it. Von Noorden calls its use in arteriosclerosis a mere French fad. However, Bühler, who has used it in 266 cases of this affection, sees unquestionable and permanent benefit. The local high frequency uses, notably in urology, are naturally better founded, as they represent a type of electrosurgery. In this connection the work of Beer and that of Bugbee, both of New York, is quoted. The former's activities in the field of vesical tumors are well known, while Bugbee gets good results in prostatic obstruction. Diathermy is a rational application of high frequency, but it has been overdriven and full-fledged textbooks were issued before the method had been thoroughly tested. Many Germans have taken up diathermy with enthusiasm. It seems to have no special indications and it represents no new therapeutic principle, since thus far it only stands for thermotherapy, like the hot air chest. One should be very skeptical concerning its deep action, although it is better applicable to certain regions like the internal ear than ordinary heating apparatus. General diathermy may also be superior to simple heat in low nutrition, in convalescence, etc., especially when there are unresolved collections and circulatory stagnation. The author is no less critical of Bergonisation, which is largely an exploitation of apparatus for universal usage in advance of thorough

scientific testing. It appears, like d'Arsonvalisation, to have aroused the antagonism of von Noorden (who on his part has pursued an identical course with radium). The author claims that Bergonisation is not used by itself for reducing flesh and that when it has been used alone not much loss is recorded. The subjects diet as usual. It is justly claimed that diet and active exercise suffice amply for the treatment of corpulence. Naturally resources like the preceding may give good results in special conditions and special subjects. They should be given a trial in supposedly incurable diseases and in patients who do not respond to other measures—for example in spondylosis rhizomelique.

Relation of Dressings to Wound Infection.—Gelinsky refers to the employment of dressings which are calculated especially to prevent the infection of wounds. He states that primary infection in warfare is insignificant, the danger lying in secondary infection. This peril increases rapidly with the size of the wound, the amount of shredding, the duration between injury and the first dressing. The latter should naturally be practiced at the earliest possible moment. In regard to removal of tissues which would become infected, this could involve mutilations which dare not be practiced. The greater the amount of tissue removed the less the chances of infection, but we cannot amputate limbs to save life until life is actually threatened. About all we can do is to remove all that is to the naked eye distinctly foreign material. Iodine, etc., can only prevent spread at the wound margin. The germs in the wound itself must be left wholly to the animal defences. With wounds of small opening we can do this with confidence, even when there is crushing of tissue. In these cases iodine destroys some of the germs and an occlusive dressing prevents new infection. Otherwise viewed our combined resources are as follows: asepsis throughout; rest (secured by posture, splinting, etc.); antisepsis as an inhibitant of germ proliferation (in powder form); drainage, after proper incision, with gauze and wet dressings allowed to evaporate; hyperemia, in any obtainable manner. Early, intensive treatment should imply a minimum of infection, but this is an unknown X, the capacity to resist infection.

Open Puncture of the Pleura.—Schmidt understands by open puncture the use of a simple trocar for evacuating a pleuritic exudate. There is no application of the aspiration principle, and no obstacle to the free entrance of air. He regards this method as the only rational one. In regard to technique only enough air should be admitted to offset the disturbance of pressure relations consequent upon removal of a certain amount of fluid. The air should not be forced in under pressure with the aim of forcing the fluid out. This may be a good principle to employ for cleaning beer barrels but is at least unnecessary in human pleurisy. Puncture should be made at the most dependent point as the patient lies on his side crosswise between two beds. The introduction of air does much to prevent the severe consequences of pleurogenous reflexes, and further serves to prevent adhesions and thickening of the visceral pleura. The possible consequences of irritation or puncture of the latter by an aspirating needle are summed up by the author as cough, syncope, edema of the lung and albuminous expectoration. The admission of ordinary unfiltered room air will have no bad effects in the pleura. The author not only eliminates all aspiration and filtration apparatus but sees no need for manometers. As long as air enters the pleura spontaneously there will be no disturbance of pressure equilibrium. If the exudate is pent up only enough will escape to neutralize the pressure in the pleura. Air then enters with inspiration and a little fluid escapes at each expiration. There can be no increase of pleural tension unless the operator suddenly withdraws the trocar at the acme of expiration. If an exudate is under negative pressure encapsulation must have occurred; puncture cannot cause collapse of the pleura for just enough air enters to raise the pressure to 0. Exudate flows through the puncture like water from a bottle. In hemothorax there is no contraindication of puncture. The same technique is recommended for diagnostic puncture. The author, who is an internist and not a surgeon, has been cautious in recommending his method as a routine measure, although it is within the reach of every practitioner. The remote results of a number of men have yet to be worked out.

Treatment of Large Wound Surfaces.—Schaedel speaks of war as causing a "traumatic epidemic." As in all epidemics we have a chance to use competitive procedures, compare them and choose the better ones. The one great aim is to make it possible for the injured to return to the war game at the earliest possible moment, or in other words conserve and restore his efficiency. From this viewpoint there are two classes of wounds, viz., those of the bones and joints and those of the soft parts. In the latter healing of the wound means return of efficiency, but not so in the former, for after healing we see stiff joints, etc.; so that we may speak of simple and complicated injuries. In large simple wounds it is seldom necessary to resort to skingrafting with its delays. The ideal dressing is that which takes care of the secretions without disturbing the young epithelium. A wall is built up about the granulating surface with adhesive plaster, and this protects the latter from friction and other insults. All fracture dressings must have the aim of enabling the patient to move about freely (but if there are simple wounds of the calf these do better under rest in bed). Plaster dressings are used freely in fractures, both for splinting and protection. Fenestration is necessary to give lightness and accessibility. Various artifices are useful to prevent soiling of the fixed dressings by wound discharges, such as the use of mineral fats. Bone splinters are never forcibly removed, for these often aid in the healing process. Tube drainage is used for fistulæ with balsam of Peru to hasten closing. Fever is an indication for slitting up to locate a pus pocket. Nothing improves the general condition so much as getting about on the legs.

Münchener medizinische Wochenschrift.

July 6, 1915.

Cadaveric Rigidity and the Physiological Processes in Muscle.—Wacker sums up his serially published study as follows: After cessation of the circulation there sets in a rapid disintegration of glycogen in the muscles which is dependent on the temperature. If the body is kept warm after death it sets in within a few hours, while application of cold can arrest it almost completely. On the rapidity of the process are dependent the point at which cadaveric rigidity begins and the duration of the process. The degree of rigidity depends on the state of the muscles at the moment of death. Certain metabolic disturbances, as in cachexia, antagonize the rigidity because the muscles no longer contain glycogen. As the latter disappears muscle alkalinity is diminished, while lactic acid increases and neutralization occurs. The quantitative relations and graphic representation of the processes indicate that lactic acid is derived from glycogen.

Theory of Graves's Disease.—Oswald, as a result of studies by recent authors, comes to the following conclusions: The old champions of the neurogenic theory

have received new support. Claude Bernard produced exophthalmus by stimulating the cervical sympathetic; Filehne got the same result by stimulation of the medulla, while Charcoi showed a relationship between Graves's disease and the psycho and central nervous system. The alimentary factor is the most obvious one, but next in order comes the neurogenic. Naturally the new doctrines of vagotonus and sympathicotonus have assisted in the rehabilitation of the neurogenic theory. We know that the other endocrinic glands are also under the influence of the nervous system, but do not yet know their relations to Graves's disease. The suprarenals secrete a sympathicotonic substance, but it is doubtful whether they can help in the causation of Graves's disease because we often find a hypoplastic state of the adrenals in the latter. But the reciprocal relations of the endocrinic glands are too little understood to enable us to speak offhand in the matter. Equally obscure are the relations between thyroid and thymus.

A Remarkable Case—Activation of an "Unsuccessful" Vaccination by an Injection of Diphtheritic Antitoxin.—Eggebrecht reports a case which occurred in a "plague hospital" or "military pesthouse," and states that he has had no opportunity to look up literature. The subject of the paper was a soldier originally qualified for active service at the front, but who as a result of military hardships had been assigned to laundry work. He had twice proved refractory to vaccination, and his subsequent typhoid and cholera vaccinations had called forth no suspicion of local or general reaction. While doing laundry work in February last he developed diphtheria and received 1000 units of antitoxin. His last vaccination against smallpox dated from October. Four days after receiving antitoxin the scratches of his most recent smallpox vaccination showed activity, reddened, and formed papules. Pustules did not develop and the papules underwent involution. Vague as were the phenomena they appeared in every way to represent a belated abortive vaccination, four months delayed. There is every reason to believe that the virus had slumbered in the scratch wounds on the forearm. The latter seem never to have undegone final cicatrization. To explain the action of diphtheria serum in rousing this latency the author invokes the aid of expert immunologists, and doubtless some of the latter will soon be heard from.

Deutsche medizinische Wochenschrift.

July 1, 1915.

Conception of Child Neuropathy and Its Limitations.—Stier states that the study of psychic-neurotic disorders of childhood is still young. The pediatrist is interested in the special subject of spasmophilia while the neurologist leans chiefly towards psychopathology. Disease having a somatic basis can be recognized readily even in very young children, but in psychic-neurotic disorders recognition is not so simple a matter because normal development in this province has not yet occurred. A nursling born without a brain behaves in the same manner as a normal newly born. Not until it is time for it to make grasping efforts, etc., is the difference perceptible. The author refers specifically to Hübner's celebrated brainless newly born which during its short period of life behaved like a normal nursling. At birth one nervous mechanism, the reflex, is ready for use; further, perhaps, spontaneous instinctive acts which have to do with self-preservation. Other functions have to wait upon structural development of ganglion cells, etc. This follows along ontogenetic and to a less extent along phylogenetic lines. Confusing as the picture is we are able to isolate three classes of phenomena from the developmental standpoint. First, neuropathic disorders, *i.e.* disturbances of the phylogenetically oldest function, the only one in readiness for activity at birth,—simple reflex mechanism. Second, psychopathic disorders, or disturbances of the phylogenetically younger functions—the impulse and instinct life common to all of the species. Third, intellectual disorders—disturbances of the phylogenetically youngest functions. These disorders have a stratification dependent on the degree of development. Reflex activity may be increased or lessened in theory but in practice it is overexcitability which is at the bottom of most of the reflex disorders of infancy and childhood. This overexcitability causes not only a morbid intensity of the reflexes but irradiation to more remote localities. Bright lights, loud noises, mechanical shocks, contact, in addition to local reflexes—as closing the eyes—cause the nervous child to start abruptly, and even its entire musculature may be involved. Motor restlessness is doubtless also due to reflex overexcitability. The normal infant smiles and is responsive when it is fed and tended, while the neuropathic child under the same circumstances becomes restless, moves its head, hands and limbs, rests on one foot, takes a foot in its hands, "weaves" to and fro, snatches its bottle and may then drop it. It tires easily and concentrates with difficulty. Sleep disorders are a third consequence of increased reflex excitability. The child has hard work to fall asleep and is easily aroused. It tosses about in its endeavor to find a comfortable position. Somniloquy, somnambulism and pavor nocturnus, however, indicate something more serious than mere overexcitability. Spasmophilia or the tendency to convulsions is closely related to reflex overexcitability, and the latter should be present to render the former possible. Special stimuli and mechanisms, however, characterize spasmophilia. Reflex overexcitability is manifested in the vasomotor as well as the cerebrospinal system, so that the neuropathic child blushes and pales, is sensitive to heat and cold, perspires freely, suffers from polyuria and anomalies due to gastric oversecretion, has palpitation, tachycardia, and cardiac arrhythmia. Other functional disturbances due to exalted reflex excitability are enuresis nocturna and erections. A secondary consequence of overexcitability is seen in the formation of disinclinations which resemble those of older individuals but are not natural to very young children. Certain odors may cause nausea. Oversensitiveness to noises may react seriously on mental development. The child is never sensitive to its own noises. Certain movements, as seesawing, rocking, traveling on steam cars, etc., cause vertigo. Sensitiveness of the skin toward irritants is pronounced. Tight clothing causes itching, mere contact of the fingers with plush garments or the sound of sawing through a nail will cause intense creeping of the flesh. The author does not pursue his subject beyond disordered reflexes.

Diplococcus Septicemia and Proliferative Activity of the Hematopoietic Organs.—Giovanni Ollino reports a case of acute leucemia in a man aged twenty-eight years in which the diagnosis was established by blood examination and confirmed at autopsy. There was isolated from the blood an encapsulated diplococcus whose virulence was demonstrated by animal inoculation. The author does not attribute any etiological relationship between this microorganism and acute leucemia. He notes however that various organisms have been isolated from the blood in acute myeloid leucemia: by Sternberg a streptococcus; by Woswinkel and Duzelt, a microorganism classified as the *Bacillus paratyphus B;* and by Barreschen, a staphylococcus.—*Annali dell' Istituto Maragliano.*

Insurance Medicine.

Total Abstinence in Relation to Insurance.—In the year 1840 Robert Warner, a member of the Society of Friends and a total abstainer from intoxicating liquors, applied to an English life insurance company for a policy. The directors made a condition for granting the policy that he pay 10 per cent. more than the ordinary premium because, as they viewed his case, he was "thin and watery and mentally cranked in that he repudiated the good things of God as found in alcoholic drinks." Warner refused to accept the dictum of the company that made total abstinence a handicap, and founded what is known as the United Kingdom Temperance and General Provident Institution to insure the lives of total abstainers. In 1848 the company extended its field so as to cover very moderate drinkers, who were carried in a separate class and very full statistics have been kept of the two departments.

Robert Mackenzie Moore, actuary of the company, read a paper before the Institute of Actuaries on November 30, 1903, which is summarized by Joel G. Van Cise, actuary of the Equitable Life Assurance Society of the United States, in an address before the Actuarial Society of America.

The figures given in the report, he says, include the entire experience of the office to the end of the year 1901, thus covering over sixty years in the case of abstainers and over fifty years in the case of non-abstainers. There are two important points to be noted: (1) That there has been no marked difference in the number of policies in force in the two sections. (2) The average amount of the policies in each section has been about the same, so that the comparison of the experience would seem to be as fair a one as could possibly be made. The following are the figures: Male lives, non-abstainers—total number of years of exposure to risk, all ages, 466,943; expected deaths by our table, 8,911; actual deaths, 8,947; per cent. of actual to expected, 100.4.

Male lives, abstainers—total number of years of exposure to risk, 309,010; expected deaths by our table, 6,899; actual deaths, 5,124; percentage of actual to expected, 74.3.

An instructive comparison in the report is that of mortality at various ages, as given below. Ages 20-30. Number of deaths total abstainers, 4,221; moderate drinkers, 4,677; excess deaths among moderate drinkers, 465.11 per cent. 30-40. Total abstainers, 4,201; moderate drinkers, 7,041; excess deaths among moderate drinkers, 2,840, or 68 per cent. 40-50. Total abstainers, 6,246; moderate drinkers, 10,861; excess deaths among moderate drinkers, 4,615, or 74 per cent. 50-60. Total abstainers, 13,056; moderate drinkers, 18,521; excess deaths among moderate drinkers, 5,468, or 42 per cent. 60-70. Total abstainers, 29,078; moderate drinkers, 34,568; excess deaths among moderate drinkers, 5,409, or 19 per cent.—Samuel Oelson in the *Outlook*.

The Increasing Need of Life Insurance for Women.—The problem of the insurance of women has been ever one of interest and difficulty due to the lack of knowledge we have been able to bring to bear upon its solution. At a very early period woman as an insurable subject was considered most desirable; at another period—the companies having insured her at a lower premium rate than men because of her supposed superior longevity—we find her attractiveness quite dispelled by the unfavorable mortality experienced. At still another and later period we find her again sought by life insurance companies, until at the present time practically all barriers to her acceptance have been removed. Mr. Herbert C. Cox, president of the Canada Life Assurance Company of Toronto, Ont., thus gives the history of women as risks in the insurance world. In 1742 Kersseboom, in his investigations into the mortality of the Dutch Annuitants, made special note of the greater longevity among females, and his data confirmed the fact. Up until 1843, on account of this increased longevity, the insurance companies offered lower rates to women, which proved to be a mistake, for in that year the tabulated experience of 17 British offices demonstrated that this longevity failed to assert itself in the case of insured women.

In 1861 the compilation of the well-known Combined Experience Table of Mortality led to the conclusion that the greatest reliance could be placed upon a table which was based upon observation of male lives exclusively, as the mortality among insured females had been clearly shown to be higher than among insured males. The recent investigation made by the Actuarial Society of America further confirms this finding, although the superior longevity of women in general is still unquestioned. This wide divergence in experience may be due to the fact that only women who presented themselves were insured, the companies making no effort to seek women as risks, or to force insurance upon them, as is done with men. Probably less than 7 per cent of insurance risks are upon the lives of women. This surely cannot be considered a fair proportion, having in mind how very extensively woman has been thrust into the professional and industrial occupations by our modern civilization. In all of the professions, in finance, in commerce, in manufacture, and even now in war, the twentieth century woman is bearing her full share in the creation and conservation of the wealth of nations, and in the support of those for whom circumstance have rendered her responsible. Every basic argument in support of insurance for men serves also to impress the necessity and desirability for similar protection for women producers. In addition and of equal importance is the economic value to the State of having insured those women who have established for themselves a monetary value through becoming the support of others who may eventually, but for the aid of life insurance, become a charge upon the State. Entitled to consideration and insurance benefits are numberless women of the home, whose lives represent a value which cannot be expressed in terms of money, but who, nevertheless, present an indisputable insurable interest.

It would seem, therefore, that the life insurance companies have a duty to perform in respect to the women—all women—who have assumed their responsibilities to the State and society in whatever form it may be; there should be set in motion whatever of machinery we may have or be able to devise, having always in mind that it is laid upon them by their relation to the State to make, even at the cost of some individual discomfort, ample or possible provision for the perpetuation of their earning capacity in its application to others.—The Association of Life Insurance Presidents, New York, December, 1914.

Book Reviews.

THE OPERATIVE TREATMENT OF FRACTURES. By Sir W. ARBUTHNOT LANE, Bart., M.S., F.R.C.S. Senior Surgeon to Guy's Hospital and Emeritus Surgeon to the Hospital for Sick Children, Great Ormond street. Second Edition. 184 pages, with 226 illustrations. Price, $4.00 net. London: The Medical Publishing Company, Limited. Chicago: Medical Book Co. 1914.

THE second edition of Lane's work differs but little from the first, for he has merely added such radiograms as he felt would be of service in demonstrating more clearly the best mode of reduction of fragments and their retention in position. Lane's views as to the operative treatment of fractures by screws and plates under varying conditions are given in detail, and the numerous illustrations make each important point clear.

While the popularity of the Lane plate method of treating fractures of the long bones reached its zenith and began to wane in this country at about the time when the inlay bone-graft technique was being developed and while this latter has now become the method of choice with perhaps the majority of progressive American surgeons, and particularly in the treatment of ununited fractures, Lane says: "In my experience it is very rarely necessary to employ bone grafts in the operative treatment of ununited fractures, since the metal bone plate is in the vast majority of cases the best and most efficient means of establishing union." Lane's own results in the use of the plate have been very much better than those of any other operator; hence he is justified in retaining an enthusiasm for the method that cannot be shared by others. There can be no doubt that this book is written in accord with his honest convictions and it is thus one of great interest to all surgeons who may be called upon for the operative treatment of fractures.

THE NEW STANDARD FORMULARY. Comprising in Part I all Preparations official or included in the Pharmacopœias, Dispensatories, or Formularies of the World, together with a vast collection from other sources; the parts following embracing Domestic and Veterinary Remedies, Proprietary and Synthetic Remedies, Perfumes and Toilet Articles, Soda and other Beverages, and Domestic Utilities. By A. EMIL HESS, Ph.G. and ALBERT E. EBERT, Ph.M., Ph.D. Chicago: C. P. Engelhard & Company, 1914.

THE scope of this volume is briefly set forth on the title page, of which the above is a transcript. It comprises 1,256 pages, the subjects being arranged alphabetically. The divisions of this work are as follows: Part I. Pharmaceutical Preparations. Part II. Domestic and Veterinary Remedies. Part III. Synthetic and Proprietary Preparations. Part IV. Perfumes and Toilet Articles. Part V. Soda Fountain Beverages. Part VI. Domestic Utilities. With encyclopedic comprehensiveness there is presented a survey of everything in the drug and pharmaceutical line from purgative powders to putz pomades. The book is primarily for the use of the apothecary but the physician will find in it a good deal to satisfy his own wants. There can be no question that this work supplies a distinct want in the medical library. It is a veritable storehouse of prescriptions and special formulæ.

THE EXTRA PHARMACOPOEIA of Martindale and Westcott. Revised by W. HARRISON MARTINDALE, Ph.D., F.C.S., and W. WYNN WESTCOTT, M.B., Lond., D.P.H. Sixteenth Edition. In two volumes. Price, Vol. I, 14s.; Vol. II, 7s. London: H. K. Lewis, 1915.

THE authors state in their preface that the notable progress in the sciences with which the Extra Pharmacopoeia is concerned . . . renders it imperative that the work should be divided into two volumes as in the case of the last edition. A large portion of the book has been rewritten but without increasing its size, and experimental research has gone hand in hand with the study of the scientific literature.

Volume I includes everything the physician and pharmacist are likely to require for immediate reference on therapeutic matters. This volume also contains the chapter on vaccines, the section on organotherapy, a supplementary list of drugs, a list of the most potent antiseptics, and the present legal conditions governing the sale of poisons in Great Britain and Ireland. At the end of the volume is a general posological index referring to the two volumes and an extended therapeutic index of diseases and symptoms.

Volume II contains analytical addenda to the materia medica described in the first volume; a list of proprietary medicines with their approximate compositions; a list of mineral waters with their chemical constituents and medicinal uses; analytical memoranda for the examination of urine, blood, and feces; the antiseptic power of numerous chemicals and disinfectant preparations for surgeons' use; methods of water and milk analysis; and extensive bacteriological and clinical notes.

The present edition of the Extra Phamacopoeia has been brought into accord with the new British Pharmacopoeia and a table is given of the more important changes which have been made. The scope and amount of information contained in these small volumes is truly remarkable: they will prove helpful both to physicians and pharmacists, and may be recommended without reserve.

QUAIN'S ELEMENTS OF ANATOMY. Eleventh Edition. Editors, Sir EDWARD ALBERT SCHÄFER, LL.D., Sc.D., M.D., F.R.S., Professor of Physiology and Histology in the University of Edinburgh; JOHNSON SYMINGTON, M.D., F.R.S., Professor of Anatomy in the Queen's University of Belfast; and THOMAS HASTIE BRYCE, M.A., M.D., Professor of Anatomy in the University of Glasgow. In four volumes. Vol IV, Part I. Osteology and Arthrology, by T. H. BRYCE. Pages 329, with 247 text figures and 28 colored plates. Price, $3.75 net. London, New York, Bombay, Calcutta, and Madras: Longmans, Green and Co., 1915.

THE same careful and painstaking attention to detail and accuracy of statement that has marked all previous editions of Quain's anatomy is quickly apparent even upon a cursory examination of this volume. The text has been thoroughly revised, new sections have been added on the development of the skeleton, and a bibliographical list covering the more recent literature on osteology has been added. The 28 full page colored plates accompanying the section on arthrology form a valuable aid to the interpretation of the text. The Basle nomenclature has been in great part adopted and, in short, the division of anatomy embraced in this volume has been most thoroughly covered.

THE GOLD-HEADED CANE. By WILLIAM MACMICHAEL, M.D. With an Introduction by Sir WILLIAM OSLER, M.D., F.R.S., and a Preface by FRANCIS R. PACKARD, M. D. Price $3.00 net. New York: Paul B. Hoeber, 1915.

THE early years of the nineteenth century saw the publication of a numerous family of books of this type. Whimsical, ingenious, often amusing and as often dull, most of them are now known only to collectors, whose shelves may hold "Chrysal, or the Adventures of a Guinea," the "Memoirs of an Old Wig," "The Interesting Adventures of a Hackney Coach," "The Recollections of an Old Umbrella," and others of like spirit. The best of the lot, if successive editions be a test of value, was "The Gold-Headed Cane," first published, by John Murray, in 1827. A second edition appeared in 1828, and a third, by Longmans, in 1884. The present reprint is the fourth.

The story of the cane, owned successively by Drs. Radcliffe, Mead, Askew, Pitcairn, and Baillie, and covering the period from 1689 to 1825, is interesting alike to the lay and to the medical reader. The reprint of a literary and medical classic such as this, requires no apology. The book is attractively printed and bound, with a slip-case.

UEBER DIE VERSORGUNG UNSERER VERWUNDETEN IM FELDE. Vortrag gehalten am 11 April 1915 im Saale des Abgeordnetenhauses von Dr. W. KÖRTE, Generalarzt, berathender Chirurg des III Reservekorps. Preis 1 Mark. Berlin: A. Hirschwald, 1915.

THE Third Reserve Corps was actively engaged on the Western frontier from August 17 to November 30, and was thereupon transferred to the Eastern frontier where it participated in heavy fighting for several weeks. Since that period only minor engagements have been fought. The fierceness of the hand-to-hand warfare was shown by the great number of wounds made by sabres and bayonets. The organization of the medical department, the routine management of the various injuries and their sequelæ, have of course been thoroughly covered by the medical press and present nothing new. The author cannot speak too highly of the bravery and fortitude of the plain soldier. The horror of the warfare he will not attempt to depict, as it is best left untold. Not a word is said against the enemy, and nothing in his praise, for the writer deals as his title denotes solely with the German wounded of a single army corps.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Fortieth Annual Meeting, Held at White Sulphur Springs, West Virginia, May 18, 19, and 20, 1915.

THE PRESIDENT, DR. THOMAS J. WATKINS OF CHICAGO, IN THE CHAIR.

The Present Status of Ovarian Transplantation. — Dr. FRANKLIN H. MARTIN of Chicago drew the following conclusions, based on his own experience and on the literature of the subject: (1) Subcutaneous transplantation of ovarian tissue did not increase the risk of operation. (2) In the majority of patients the graft would persist for a time. In one series it was still present, at twenty-seven months, eighteen months, and in three others more than a year. (3) In some patients it appeared to functionate as shown by the apparent development of Graafian follicles, by variation in size and tenderness, and, when the uterus remained, by menstruation. (4) The presence of one ovary in the pelvis did not necessarily interfere with the success of the graft. (5) Those patients in whom ovarian tissue had been grafted seemed to have less discomfort from the premature menopause.

What Is the Fate of the Ovaries Left "in Situ" after Hysterectomy?—Dr. HIRAM N. VINEBERG of New York City read this paper, of which the following were the conclusions: (1) There was considerable uncertainty as to which tissue in the ovary was responsible for the production of the internal secretion. (2) While it was established that the follicles went through the various stages of development in the conserved ovary or ovaries after the uterus had been removed, it was not at all certain that the function of the internal secretion continued uninfluenced by the great changes in the blood supply and by the traumatism to which the pelvic sympathetic nerves were subjected as a consequence of the operation. (3) It was still a disputed point as to what degree the climacteric syndrome was due to the removal of the ovaries, and to what degree of injury to the pelvic nerves incident to the operation. (4) Clinically, it had been found that the freedom from the climacteric syndrome in hysterectomized women, in whom the ovaries had been conserved, was only relative to that which obtained in the same class of women in whom the ovaries had been removed. A generous estimate would be 20 per cent. in favor of the former. (5) To obtain the benefits claimed by the advocates of conservation, the ovaries should be retained at all ages and not limited to those under forty years, as was done by most of them, inasmuch as it had been shown that of women who suffered most severely from the artificial menopause, 46 per cent. were only forty-five and over. (6) Subsequent disease of the conserved ovary, such as cystic degeneration, malignant growth, inflammatory processes, leading to adhesions, and pain calling for a second operation, did occur in some cases, the number no doubt being much larger than would be inferred from the records found in the literature. (7) In view of the foregoing conclusions, he was of the opinion that the doubtful clinical advantages accruing from retaining the ovaries in hysterectomy were more than counterbalanced by the risk to which the patient was subjected from subsequent disease and adhesions of the conserved ovaries. He would, therefore, not retain the ovaries in any case of hysterectomy unless he could leave enough of the lower segment of the uterus with its endometrium to insure the function of menstruation; for in his experience the knowledge imparted to the woman that her ovaries had not been removed had but little significance or moral effect when she learned that she would no longer menstruate.

Dr. FRANK F. SIMPSON of Pittsburgh stated that the first instance of transplanted ovarian tissue was one that encouraged them in this line of work. The patient, a young woman of considerable importance in the community, in the thirties, had a perforated appendix, with drainage for general peritonitis. The appendix was removed. Later there were adhesions about both adnexæ, which were treated. Six operations were done by leading general surgeons of New York. The young woman was a confirmed invalid. She suffered intensely at the menstrual periods. She, her father and mother insisted upon immediate removal of the uterus and adnexæ. He could not consent to do that for a period of almost a year. Every effort he was capable of was made to relieve the suffering by local and other measures. At the end of that time she suffered as much as she did at the beginning. With the full understanding of the parents and the young woman that this work was in the experimental stage, he consented to remove the pelvic structures. He did not transplant the ovary into the abdominal cavity, thinking it would cause serious trouble, and that disintegration of the ovarian tissue or infection might readily cause serious damage requiring a second abdominal operation. So it occurred to him to transplant it beneath the skin. He used the adnexæ, transplanted about one-half of the ovary; it lived, and to-day was quite the size it was when transplanted. On a number of occasions he had felt the ovary and, he believed, the Graafian follicles. In that young woman the functional result was good. Instead of being a confirmed invalid and lying in bed, she was about, was vigorous, and practically not harmed at all by the disagreeable phenomena of the precipitated menopause.

Dr. JOHN O. POLAK of Brooklyn had four unreported cases of transplantation of the ovary. In three of them the entire ovary was transplanted in a pocket in the pre-vesical space. Two of those had caused no trouble so far as the ovarian graft was concerned. This graft seemed to have had no effect on the symptoms of the menopause, that is, the woman suffering from convulsions and the other nervous phenomena. A third had become cystic, and he had seen that woman recently. She had a cyst in that locality about the size of a two months pregnancy. She was the only woman of those three who had had relief from the symptoms of the menopause. His fourth case was not an implantation of the whole ovary, but a graft of the ovary into the cornu of the uterus at the point of excision of the tubes. This patient menstruated for nine months, and then menstruation ceased. She then developed all the symptoms of the post-climacteric with considerable severity and gradually those had passed away.

Dr. J. WESLEY BOVEE of Washington, D. C., said that the ovary floated freely in the peritoneal cavity, and we knew it was the history of an ovary that became encased by adhesions, and not necessarily by marked infection, that it began to undergo sclerocystic degeneration. When we transplanted those ovaries we covered them entirely with tissue, and what was to his mind a very reasonable result was they would undergo degeneration, and he did not believe himself that the results were good or would be good so long as that plan was followed. When they resorted to transplantation of ovarian tissue, it must be done in such a way as to give freedom to such tissue.

Dr. HIRAM N. VINEBERG of New York City said he had had two cases of autotransplantation of the ovary, in which he took a small wedge-shaped piece of the ovary and inserted it into the lower abdominal wound, leaving it in between the fat and the skin. In one of those cases the operation was done nine months ago, and in the other about six months ago. There had been absolutely no difference in the healing of the wound. So far as one could tell from frequent examinations since then, one would not know that transplantation had been done.

Dr. JOHN J. CLARK of Philadelphia said there was no organ that had such a shifting circulation as that of the ovary and no organ whose circulation was so rich. In the little transplantation work he had done personally, he had endeavored to expose the cortex, to lay open the ovary, pulled it open as one would a kidney, and allowed the vascular portion of the ovary to come into direct contact with the peritoneum which he had utilized, and not the subcuticular tissue as Dr. Simpson had done, and thus far his experience had not been particularly satisfactory.

Dr. HERMAN J. BOLDT of New York City said those who had had a large experience with conservative surgery of the adnexa must have come to the conclusion which those who had read the papers had come to and the others who had spoken, and yet in view of the fact that there were undoubted instances where the symptoms of the menopause were at least ameliorated if a seemingly normal gland was conserved either by ordinary conservatism or by transplantation, he personally felt he wanted to continue that line of work. On the other hand, he could only say in those instances where conservatism had been practised, he had had the same disagreeable features to contend with that others had had. He recalled two instances where it became necessary for him to reopen the abdomen and to

remove an ovarian cyst from the ovary which had been retained, and he could not recall any instance where the removal of cysts had been more difficult than in those two cases. However, as he had said, there were instances where the symptoms of the menopause were at least ameliorated and where they were entirely absent.

Dr. J. Riddle Goffe of New York City said that about twelve years ago he made his first adventure into this field of work. It was on a young woman whose tubes were absolutely destroyed by disease. She came from Buffalo and she was anxious to have children. Her husband was equally anxious that she should have children. With this idea in mind of future offspring, he removed both tubes and one ovary; then he slit open widely the whole fundus of the uterus, being careful to preserve the mucosa of the salpinx in his obliterating operation, and to retain as far as possible the lymphatics and the arterial nutrition of the ovary. Without splitting the ovary, he turned it right around and hung the ovary free in the uterine cavity. He kept track of the patient for about six months. She had a slight discharge of blood at the regular time of menstruation once; then she escaped from his observation and he had not been able by correspondence in any way to get any further information in regard to the case.

Dr. Joseph Brettauer of New York City thought each case for ovarian transplantation ought to be individualized. To some women of a nervous temperament or who were neurasthenic the removal of the ovaries was a more serious matter than it was in other women who were not so constituted physically, and he thought it was very essential to individualize the cases and in this way they might come to some definite conclusion.

Dr. Willis E. Ford of Utica, N. Y., said he was temperamentally rather pessimistic about leaving parts of ovaries. His experience had rather prejudiced him against it.

Dr. Philander A. Harris of Paterson, N. J., said it had been his rule in removing the uterus to leave an ovary or both ovaries, if possible. In short, he left all the tissues that were healthy. That might be right, or it might be wrong. He was rather encouraged when he heard Dr. Goffe speak of having placed a piece of ovary in the uterus, but the question arose in his mind whether, if the woman became pregnant, it would not cause a rupture of the uterus. He thought he would worry over that.

Dr. Boldt would like to know if any member knew of any cases where, after an ovary had been left and the oviducts removed, the patients had subsequently become pregnant? That question had been raised a number of times.

Dr. Bovee stated there were plenty of them on record.

Dr. Boldt said he had not seen such a case himself.

Nitrous Oxide in Labor.—Dr. N. Sproat Heaney of Chicago said that during the last ten years Dr. J. Clarence Webster at the Presbyterian Hospital had been largely substituting nitrous oxide gas and oxygen for ether in obstetrical work. Versions, forceps, cesarean sections, and various other obstetrical operations were performed under this anesthetic when it seemed better suited to the condition of the patient than ether. He also used it early for the conduct of normal labor in the second stage, allowing the patient a light degree of anesthesia during pains, with a return to the normal state between pains. Lynch in August, 1913, began to use nitrous oxide gas and oxygen in labor and subsequently the speaker began independently to use it. With a proper machine and a nasal inhaler, nitrous oxide might be given to the extent that the patient did not experience pain during labor, and yet maintain consciousness and if needs be she could follow the directions of the attending physician. If oxygen was administered at the same time this stage of analgesia was more easily maintained and the headaches sometimes complained of after pure nitrous oxide were much more infrequent. To insure absolute painlessness the gas might be given to the surgical degree during the last few pains, or if, as infrequently happened, the birth began to advance too rapidly, ether might be mixed with the gas or substituted for it. The amount of gas necessary for the conduct of a case varied greatly with the type of machine used. The cost of the gas might be materially lessened in hospitals by the use of the large cylinders. For outside work, an efficient portable apparatus which with cylinders would fit in a suitcase was made by several different manufacturers. Nitrous oxide and oxygen analgesia might be given just as efficiently in a home as in a hospital. No expert anesthetist was necessary. From his observation and that of the members of the Presbyterian Hospital staff, he believed that in nitrous oxide and oxygen analgesia they had not only an efficient means of controlling the suffering in labor, but also a safe means, free from all the well known and valid objections advanced against other means of securing painless labor.

Dr. John O. Polak of Brooklyn, N. Y., asked Dr. Heaney if it was possible to continue nitrous oxide gas from the very beginning of labor as an analgesic method, and about what would be the approximate cost of conducting a twelve to twenty-four hour first stage with it, and how much personal attention the obstetrician would have to give in the management of the case?

Dr. Willis E. Ford of Utica, N. Y., wanted to know whether there was any cyanosis in the children, or whether there was more cyanosis from the use of gas than from ether?

Dr. Louis Frank of Louisville said he had used nitrous oxide gas as the anesthetic of choice in his surgical work for almost three years. In this work there had been included three cases of cesarean section in which nitrous oxide gas and oxygen was given as the anesthetic. He thought the administration of nitrous oxide gas and oxygen for analgesic purposes required the services of an expert. He had considered it the most dangerous of all anesthetics that could be used in unskilled hands, while in skilled hands it was the safest. The cost of the gas was lessened materially when large tanks were used and when the gas was manufactured in the hospital.

Dr. Hiram N. Vineberg of New York City had, in one or two instances, attempted to do a plastic operation under the administration of nitrous oxide and oxygen, and the blood was so black that the field of operation was obscured. They had to stop. He did not know whether it was improperly administered or not. They had to resort to ether because the operative field was dark and they could not see what there was to repair.

Dr. Heaney, in closing, said their opinion was that during the latter part of the first stage and second stage they could give gas for sixty cents an hour. The amount of oxygen varied with each patient. It depended how quickly the woman passed into cyanosis and how much oxygen one should give. The less the amount of gas given the better. With the nose piece the cyanosis in the infant was less marked. It was hard to determine what the effect of any method was, provided the baby did not require artificial respiration. If it was blue, it cried immediately. It was very gratifying in cesarean sections to have the baby cry at once. One could then dismiss the child from one's mind and attend to the mother, a thing which one was not able to do always under ether anesthesia, in performing cesarean section.

The Management of the Placental Stage of Labor, with Special Reference to Retained and Adherent Placenta.—Dr. John O. Polak of Brooklyn, N. Y., drew the following conclusions from his study, as to the management of the placental stage and the treatment of adherent placenta: (1) The placenta would separate spontaneously if the normal mechanism was allowed to obtain. (2) Any manipulation of the uterus before the clinical evidences of separation were apparent would disturb this normal mechanism. (3) Postpartum hemorrhage was best guarded against by the observance of the physiological processes, and that partial detachment, the result of manipulation, predisposes to bleeding. (4) The normal mechanism of placental delivery was that described by Schultze. (5) The Duncan mechanism only occurred in low implantations of the placenta or where manipulation had been untimely and vigorous. (6) The placenta might be retained in the uterus for hours or days without danger to the patient, provided it was attached or completely detached, which insured that the bleeding would be negligible. (7) Asepsis was dependent upon the penetration of the uterus by the hand or instrument to infected passages, and not upon the retention of the placenta. (8) That manual extraction was only admissible in partial separation with hemorrhage. (9) In retention of the placenta without hemorrhage the cord should be cut off close to the cervix and the case watched until the time of separation was apparent, when the placenta

might be expressed by Crede while the patient was under surgical anesthesia. (10) Invasion of the uterus *via* the vagina was fraught with danger from infection, and on exploration should the placenta not be found presenting at the internal os, infrapelvic delivery should be abandoned and delivery accomplished through sterile avenues by suprapubic extraperitoneal hysterotomy. (11) When the adhesion was so great that its removal entailed the digging out of the placenta piecemeal, excision of the placental site or hysterectomy should be the choice.

Dr. WALTER P. MANTON of Detroit believed that the implantation of the placenta was, as a rule, a good deal lower that it was usually supposed. A number of years ago he took up this subject at the Woman's Hospital and by careful examination of uteri and of the placentæ later on, he found that in several hundred consecutive cases the implantation was a good deal lower than what it was put down in the text books to be. The implantation was apt to be lateral rather than frontal or partial, therefore, he did not believe that the Schultze method of delivery of the placenta was the normal one, but that the Duncan method was.

Dr. GEORGE TUCKER HARRISON of Charlottesville, Va., agreed with Dr. Manton that the Duncan method was the one that should be employed in cases in which the placenta was detached. In such cases it was employed quite frequently. As soon as the child was born, he thought it was wrong to exercise compression. Let it alone.

Dr. PHILANDER A. HARRIS of Paterson, N. J., said in speaking of retained placenta, the placenta with the cord hanging from it was allowed to remain by him experimentally, and it was found it was all absorbed. They kept the patient in the hospital for weeks and weeks, and after absorption the uterus returned to its normal condition, showing that Nature after all was a very good doctor.

(*To be continued.*)

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK

Stated Meeting, Held May 17, 1915.

THE PRESIDENT, DR. THOMAS S. SOUTHWORTH, IN THE CHAIR.

The Significance of the Presence of Acid-Fast Bacilli in the Feces of Patients Suffering from Joint Disease.—Dr. HENRY KELLER read this paper, in which were embodied the following conclusions: The acid-fast bacillus resisting decolorization with 25 per cent nitric acid, followed by 80 per cent alcohol, was a tubercle bacillus. Patients with joint tuberculosis kept on discharging tubercle bacilli for years, as long as the disease continued active. These bacilli were living and capable of producing tuberculosis in other individuals, as proved by animal inoculation. In obscure joint conditions the discovery of tubercle bacilli in the feces might be of great diagnostic significance, and the search for them should never be omitted. A patient suffering from joint disease should not be discharged as cured without a thorough search for acid-fast bacilli in the feces, and if they were found he should be kept for further observation; for this showed that there was still some activity in the disease process. In the feces the smegma bacillus was conspicuous by its absence. M. Solis Cohen was correct in asserting that the feces of tuberculous patients must be regarded as a source of contagion and always be thoroughly disinfected and that the same precautions in regard to disinfection of hands, clothing, bed covers, etc., soiled by fecal evacuations which were taken in cases of typhoid fever should be observed in the management of patients with tuberculosis. Tuberculous infections of the bones and joints, he said, often made their appearance in the guise of various other diseases, and, on the other hand, there were many instances of joint disease other than tuberculous which resembled tuberculosis so closely as to make one hesitate before making a positive judgment. While the lapse of time might clear up the matter, this, as Judson had remarked, was always at the expense of the prognosis. On account of the vast importance of suitable early treatment, therefore, any addition to our diagnostic armamentarium should be of the greatest value; and such additional aid the speaker ventured to offer in the finding of acid-fast bacilli in the feces. As the result of experimental and clinical investigation by A. J. Moraveek of the New York Diagnostic Laboratory, and himself, lasting over a year, it was his belief that the acid-fast bacillus resisting decolorization by 25 per cent. nitric acid, followed by alcohol (80 per cent.), was a tubercle bacillus, and nothing else. It had also been found that this bacillus was viable and able to grow on culture media, and that when these cultures were injected into guinea pigs they produced tuberculosis. It was ascertained that the tubercle bacillus was the only bacillus which would remain red, all others being decolorized and subsequently taking on a counter-stain. Having described the staining technique and detailed the experimental proof of the proposition stated, he gave the following deductions derived from the experimentation and animal inoculations: (1) The acid-fast bacillus found in the feces was a tubercle bacillus. (2) It was a living germ, capable of producing the disease when injected into animals. (3) No matter how the bacillus was introduced into the system, it would make its appearance in the intestinal tract, and be discharged in the feces, without necessarily producing a pathological lesion in the intestinal mucous membrane. *The Clinical and Diagnostic Significance of the Presence of Tubercle Bacilli in the Feces.* In order to study this it was necessary to select (a) cases with positive joint tuberculosis, as shown by the signs and symptoms pathognomonio of such disease, confirmed by the *x*-ray and other laboratory aids, or those with subsequent history bearing out early diagnosis; (b) cured cases of positive joint tuberculosis; (c) a number of cases suffering from affections other than tuberculosis, as controls; also dubious cases. Investigations were made in 42 cases with active tuberculosis of joints, 6 cases of cured joint tuberculosis, 9 suspected cases of joint tuberculosis, and 18 control cases, and the results showed that under normal conditions no acid-fast bacilli were to be found in the feces—also that only in active cases of joint disease were they thus present, and not in cured cases; therefore the finding of acid-fast bacilli in the feces of patients with active disease of a joint, and no active tuberculosis in any other part of the body, was of great importance in reaching a diagnosis in an obscure case. In 31 cases in which the acid-fast bacilli were found in the feces the location of the disease was as follows: Hip, 15 cases; spine, 6; knee, 6; sacroiliac, 2; shoulder, 1; foot, 1. The youngest patient with active joint disease in whose feces these bacilli were found was 2 years, and the oldest, 40 years. The shortest duration in active cases with presence of acid-fast bacilli in feces was three weeks, and the longest five years. The methods employed in obtaining specimens of feces and in preparing these for examination were as follows: The patient was given a mild laxative the night before collection, and ordered to defecate into a chamber-vessel which had been thoroughly cleaned and then washed with boiling water. The feces were to be put into a new fruit preserving jar, cleansed in the same manner; this was to be repeated for two or three successive days, separate jars being used each day, and each labeled with the patient's name and the date of collection. A small amount of the suspected feces was diluted with an equal quantity of sterile distilled water to which a few drops of phenol solution (4 per cent) had been added, and the mixture allowed to stand for twelve hours. The water was then poured off very carefully, and a small piece of the sediment picked up with a sterile platinum wire loop, and placed upon a clean slide for staining. From each specimen of feces ten or twelve slides were prepared, and a number of cultures made. The cultures were examined from the 15th to the 21st day, and some of them were injected into guinea pigs. It was a known fact that very few patients suffering from joint tuberculosis have pulminary tuberculosis. Dr. A. J. Quimby had *x*-rayed the chest in a number of his cases, to see whether he could detect any lesion, and with the exception of a few calcareous glands, such as might be found in normal thoraces, the findings were negative. It could be assumed, therefore, that it was not at all necessary to swallow sputum containing tubercle bacilli in order that such bacilli should appear in the feces. It seemed to him more likely that the presence of the bacilli in the feces of patients with active tuberculosis was due to the fact that the body, having good resistance power, was trying to rid itself of the invasion by discharging some of the bacilli into the bowel. This hypothesis was borne out by the fact observed by himself that the feces coming from the guinea pigs when they were very ill were frequently negative for tubercle

bacilli, while when they began to improve, these bacilli would reappear. Some of the animals had stopped discharging tubercle bacilli in their feces a few days prior to their death. In human beings with tuberculosis he had observed the same peculiarity. When the patients were very ill their feces contained no tubercle bacilli, but when they had improved in general health the bacilli again appeared in the feces. Whether this theory were correct or not remained to be seen. It seemed reasonable, and in his future investigations he would endeavor to test its validity.

Dr. E. E. Smith said that Dr. Keller's investigations were confirmatory of the point that if tubercle bacilli once got into the blood they would, under ordinary circumstances, appear in the feces. It was also true that if these bacilli made their appearance in the feces they might enter the blood. The propositions set forth in the paper could be divided into two parts: (1) The occurrence of tubercle bacilli in the feces, and (2) the conclusions from the facts presented. One of the most important assertions made was that all the bacilli which resisted 25 per cent of nitric acid were virulent tubercle bacilli. This fact might be applicable to human beings, but it seemed open to question whether it held true in the case of all animals, especially bovine ones. He thought we should therefore be cautious in making it applicable to all animal life. It had been stated in the paper that there appeared to be some relation between the occurrence of tubercle bacilli in the feces and the acuteness of the condition present. When a large supply of tubercle bacilli was suddenly introduced into the system of an animal, it was not surprising that it should endeavor to get rid of them by every possible channel. So, while in acute disease conditions the bacilli might be numerous in the feces, we should expect that as the condition became subacute or chronic the number would gradually diminish; so that it might require a more careful examination to reveal their presence. The paper, he thought, had distinctly advanced our knowledge, and would be of great practical service from more than one point of view.

Dr. Anthony Bassler agreed with Dr. Smith that Dr. Keller's investigations would be of great assistance in clinical work. Personally, he had had no experience with the observation of tubercle bacilli in the feces in cases of joint disease, but in pulmonary tuberculosis and tuberculous conditions of the alimentary tract he had been surprised to note how frequently the bacilli were to be found in the feces. It was a fact also that in a large proportion of cases of pulmonary tuberculosis there were found ulcerative, or at least hyperplastic, conditions in the intestinal tract.

Dr. Keller said that as to the system of an animal getting rid of a large quantity of tubercle bacilli suddenly introduced into it, he had always been careful to inject only a normal dose: usually eight minims—the maximum dose being ten minims. In cases of joint disease the bacilli were found in the feces as long as the activity of the disease continued, even if this were for two or three years. This was, therefore, a matter of importance from a sanitary as well as a diagnostic point of view. Such feces were to be regarded as a constant source of infection, and he had known of one instance in which the pet dog of a child with tuberculosis contracted the disease. As to the presence of tubercle bacilli in the feces of patients suffering from pulmonary disease, the only question was whether they got there by ingestion or through obtaining entrance in to the circulation. In his animal experimentation he had found that it made no difference by what method the bacilli were introduced into the system; no matter what the method employed, they would appear in the feces.

Twenty Uncommon Esophagus, Stomach, and Intestinal Cases; Salient Points in Case Histories; Lantern Slides.—Dr. Anthony Bassler reported these cases. Some of them were the following: Case V.—A girl of 23 had had for years "stomach trouble," consisting of pains in the abdomen, chiefly on the lower right side, which were worse half an hour after meals, and the year previous she had had an attack of what was diagnosed as an acute appendicitis, followed by inflammation of the right kidney. She was sent by a surgeon to Dr. Bassler to confirm the diagnosis of chronic appendicitis. The stomach was the most attenuated one he had ever met with; the pylorus was in the appendix region, and was not held there by adhesions. She was treated by diet, posture, abdominal support, etc., and in about four months had gained 30 pounds in weight, and was subjectively well. One year after this he was called to Pennsylvania to see her in what was supposed to be an exacerbation of chronic appendicitis. The pain she had was cramp-like in character, radiating from the right flank, and she had frequent urination. The four cardinal symptoms of acute appendicitis—local muscular spasm, febrile temperature, nausea and vomiting—were lacking. It was therefore decided to wait, and during the night the pain suddenly ceased. A week or so later the patient voided a small renal stone, and the cause of the attack was thus explained. The case was of interest on account of the position of the pylorus, and because both of her attacks had been attributed to appendicitis.

Case VI.—A girl of 18, who was very fond of sweets, had had for three months a distinct pain in the stomach after eating, lasting about an hour. This was located at the edge of the left rectus, some distance below the ensiform, and the peculiar feature about it was that if she lay down it would suddenly cease. She was anemic, and had lost ten pounds in weight. The upper part of the abdomen was board-like, and there was an area of extreme tenderness at the outer edge of the left rectus. An *x*-ray plate showed a large stomach and the pit of an ulcer filled with bismuth. With rest in bed, Lenhartz diet, bismuth and iron, she completely recovered, and had continued well for four years. Subsequent *x*-ray plates had failed to show any ulcer. In this instance there had been an ulcer in the anterior wall which if it had perforated, as such ulcers commonly did, would have discharged into the large peritoneal cavity and quickly set up a general peritonitis. The relief from pain which the patient experienced in the prone position he believed to be due to the small-sized meals which she accustomed herself to take, which, in a lax stomach, gravitated posteriorly when she was reclining, and tended to save the ulcer from irritation by foods and by gastric secretions which were markedly acid. Case IX.—A woman of 54 was sent to the speaker for diagnosis. She had pains in the upper abdomen, on the left side, which radiated into the back, and after eating, these became so aggravated that she dreaded to take food. Regurgitations and eructations were present, and during the past three weeks had been constipated. In this short time she had lost seven pounds, and she was very nervous and depressed. The stomach, liver and right kidney were in a low position. Fluoroscopically the stomach was shown to be in a state of marked peristalsis, with a defect on the lesser curvature extending half-way across the lumen, which was not due to spinal pressure, and it could be seen that the peristaltic waves were stopped at this point. The only thing disclosed by test-meal analysis was that with the double Ewald meal method the second meal showed very much less acidity; and there was no blood in the stool. At operation there was found, slightly to the left of the spinal column, a cancer which might have been started by an ulcer at that point. There was, however, a marked neoplasm, with involvement of the lymphatics, along the lesser curvature. A partial gastrectomy was done, and the patient had now been entirely well for two years. Case XIII.—A woman of 49 had had backache since girlhood and had had four attacks of nervous prostration. Five months before she came under observation she was supposed to have had an attack of intestinal grippe. She was always debilitated and constipated, and among the manifestations of her neurotic condition were coccygodynia and a nervous stuttering. There was much gas in the stomach and intestine, and she passed large amounts of mucus in her stools. By the *x*-ray it was shown that there were marked adhesions about the colon, binding down the transverse to the mid-cecum. Anyone observing such a strictured state of affairs would be apt to conclude at once that the patient could not be relieved without an operation; yet under rest, diet, atropine and tonics this woman had become substantially well, and although the adhesions were still present, her bowels were moving normally, and her nervous symptoms, as well as those of the colitis, had disappeared. Case XIV.—A woman of 46 had had aggravated symptoms referable to intestinal toxemia for twenty years. She was poorly developed and had dilatation and atony of the stomach, with marked stasis in the entire intestinal canal. An interesting feature of her case was that the entire colon was freely movable in the abdomen, having no mesenteries in the ascending or descending portions and no anchoring at the flexures; a condition which was probably congenital. When she was in the upright posture the colon took position in the lower right segment of the abdomen, arranging itself four-

ply. The laboratory tests showed that she was markedly toxic, and if there ever was a case suitable for a colectomy this was one. The entire colon had been removed seven months ago, and since then she had gained fifteen pounds and was much better in health, although, notwithstanding Lane's conclusions as to the effect of this operation on toxemia, she was still as toxic as ever. CASE XVII.—A woman of 43 had a history of many attacks of typical migraine and various other troubles. She was constipated and always passed mucus in her stools. She had much gas in her stomach and bowels, and had lost over thirty pounds. The *x*-ray showed a large cecum and a proximal transverse colon with an apparent stricture in the middle of it; presenting what had been termed "stricture with proximal dilatation." She was operated on upon that diagnosis, but nothing whatever was found at the supposed point of stricture, though the colon, up to where it was shown on the *x*-ray plate was immensely thickened. The parts were left undisturbed and subsequently the patient was treated by means of diet, massage, rest in bed, and other medical measures. After a year's time her weight had increased from 93 to 152 pounds, and to-day she was completely relieved of all her symptoms.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

WASHINGTON STATE BOARD OF MEDICAL EXAMINERS.
July, 1914.

[Answers ten (10) questions only in each paper.]

(*Continued from p.* 297.)

GYNECOLOGY.

1. What is gynecology?
2. Name the external genital organs.
3. Define amenorrhea, dysmenorrhea, menorrhagia.
4. Give the forms of vaginitis: Give the symptoms of senile vaginitis.
5. Give causes and symptoms of endometritis.
6. Give the varieties of pelvic hematocele.
7. Differentiate: fibroid tumor, gravid uterus, and ovarian cyst.
8. Give symptoms and prognosis of carcinoma of the uterus.
9. Give symptoms and diagnosis of uterine polypi.
10. Differentiate: prolapsus uteri, rectocele, and cystocele.
11. Give varieties, causes, and symptoms of uterine displacement.
12. What are the symptoms of pelvic abscess? What the prognosis?

PATHOLOGY.

1. Mention the different kinds of tumor of the uterus, with short history of each.
2. Describe progressive changes in acute yellow atrophy of the liver.
3. Discuss hydrocephalus.
4. Give short definition of the following terms: Cystocele, embolus, keloid, lipoma, sycosis, variocele, mastitis, cholemia, apoplexy and clavus.
5. Describe leukemia; what other disease does it closely resemble and how differentiate.
6. Discuss epithelioma.
7. Give macroscopical pathology of small intestines in typhoid fever.
8. What are the findings in mitral regurgitation.
9. Give pathological anatomy in chronic parenchymatous nephritis.
10. Describe fully the progressive changes in gonorrheal rheumatism.
11. What is the pathology of locomotor ataxia.
12. Describe the pathogenesis of renal calculi.

ANSWERS.

GYNECOLOGY.

1. *Gynecology* is that branch of medicine and surgery which deals with the diseases peculiar to women.

2. The *external genital organs* are: Labia majora, labia minora, clitoris, mons Veneris, and the orifice of the vagina; the external urinary meatus is generally included, though it is not a *genital* organ.

3. *Amenorrha* is absence of menstruation during the period of sexual activity.

Dysmenorrhea is unduly painful menstruation.

Menorrhagia is a condition characterized by excessive loss of blood at the menstrual period.

4. *Forms of vaginitis:* Acute, chronic, primary, secondary, catarrhal, membranous, diphtheritic, gonorrheal, tuberculous, senile, emphysematous, granular, superficial (there is no recognized classification).

Symptoms of senile vaginitis: "The *subjective* symptoms are not in any way characteristic and all the patient usually complains of is a thin, serous, leucorrheal discharge which is not profuse or constant and which is at times streaked with blood. In some cases there may be a burning sensation in the vagina, a feeling of weight in the pelvis, and a distressing irritation of the external organs of generation. Sexual intercourse is either impossible or very painful. The *objective* symptoms, on the other hand, are marked. The mucous membrane is found to be smooth, atrophied, and covered with a scanty serous secretion, while various sized spots of ecchymosis and superficial ulceration are observed scattered over its surface. Adhesions resulting from contact between the ulcerated surfaces are common, and in some cases the vaginal vault as well as other parts of the canal may be obliterated or greatly distorted."—(Ashton's *Gynecology.*)

5. "*Acute endometritis* is the result of the introduction into the uterus of septic microorganisms. This usually occurs during labor or miscarriage, or it may result from operations, such as dilatation, or from the introduction of an unclean sound. It sometimes occurs as a complication of the exanthems. If the process is severe enough, it may involve the muscular tissue underneath the mucous membrane, when it is called metritis; or the peritoneal covering of the uterus may be invaded, when it is called perimetritis. *Symptoms.*—Acute corporeal endometritis is usually attended by considerable pain, of a dull, aching character. There are constipation and vesical irritability. The pulse is rapid and temperature in some cases is very high—from 104° to 106° F. Vaginal examination reveals a patulous cervical canal with a profuse purulent discharge escaping from it. The uterus is enlarged, boggy, and tender.

"*Chronic endometritis* may result from an acute attack or it may be chronic from the beginning. One of the most frequent causes of this condition is gonorrheal infection. Chronic endometritis accompanies a variety of pathological conditions of the uterus, such as displacements, subinvolution, laceration of the cervix, and fibroid tumors. Two varieties of chronic endometritis have been described—glandular and interstitial. The *symptoms* of chronic endometritis are usually well marked. There is pain, of a dull, aching character, most evident in the back and extending down the thighs. Leucorrhea is constant, and is quite characteristic. The discharge is thin, purulent, and blood-streaked. Menstruation is profuse, and lasts usually from 5 to 7 days. The patient's general health suffers; she loses weight and becomes anemic, there is a sense of great reduction in physical strength. Headache is a very common symptom. Nervous, digestive, and circulatory disturbances appear sooner or later. Physical examination reveals an enlarged, tender uterus. The cervical canal is patulous; the external os is eroded. The characteristic discharge can be seen escaping from the cervix."—(*Cyclopedia of Medicine and Surgery.*)

6. There are two varieties of pelvic hematocele: (1) due to rupture of an organ, (2) due to the entrance of menstrual blood into the peritoneal cavity. The most common cause is rupture of a tubal pregnancy.

7. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ovarian cyst: Absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

8. *Symptoms of carcinoma of the uterus:* Presence of a tumor, pain, offensive discharge, hemorrhage, and cachexia. *Prognosis* is unfavorable, particularly after glands are involved.

9. In the case of *polypus*, the body and fundus of the uterus are in their normal position in the abdomen, a sound can be passed into the uterus, the uterine and cervical canals are not obliterated, the polypus does not bleed easily, and is not particularly sensible to pain. The *inverted uterus* shows: Absence of body and fundus from normal position, will not permit passage of a sound into uterine cavity, the uterine and cervical canals are absent, the inverted uterus tends to bleed easily, and is very sensible to pain. In *prolapse* the largest part of the tumor is above; the opening of the Fallopian tubes cannot be seen; a sound can be passed into the uterine cavity.

Polypi of cervix. "Polypoid tumors are found growing from the mucous membrane of the cervical canal, projecting into the canal or protruding from the external os. The mucous polypus is the most usual form, and is caused by cystic degeneration of the Nabothian glands of the cervical mucous membrane. Sometimes such polypi protrude from the ostium vaginæ. Less often a papillary or warty growth is found on the mucous membrane of the cervical canal, in the neighborhood of the external os. There is usually present dilatation of the external os and cervical canal. The symptoms of cervical polypi are not characteristic. Inflammation of the cervical mucous membrane and cervical catarrh may result. There may be slight, and rarely profuse, bleeding from the externl os. The bleeding may follow efforts at straining, sexual connection, long standing, or exercise. Occurring at the time of the menopause or later, this symptom would excite the suspicion of beginning cancer of the cervix."

10. For *prolapse*, see QUESTION 9. In *rectocele*, the posterior wall of the vagina is bulged forward and downward. In *cystocele*, the anterior wall of the vagina is bulged backward and downward.

11. *The varieties of displacement of the uterus* are: Retroversion, retroflexion, anteversion, anteflexion, lateral version, lateral flexion, descent or prolapse, ascent, and mallocation (to front, back, or one side).

The following symptoms may follow displacements of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be *general symptoms*, as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

CAUSES OF DOWNWARD DISPLACEMENTS OF THE UTERUS: (1) *Pressure from above* (pelvic or abdominal tumors, ascites, tight or heavy clothing, straining at stool, muscular exertion, fecal accumulations, habitual overdistention of the bladder); (2) *weakening and relaxation of the uterine supports* (subinvolution, senile atrophy of pelvic floor, abnormally large pelvis, increased weight of uterus, puerperal traumatisms, pressure from above, traction from below); (3) *increased weight of uterus* (congestion, subinvolution, metritis, pregnancy, fluid in the endometrium, uterine tumors); (4) *traction from below* (vaginal cicatrices, falling of pelvic floor, contraction and congenital shortening of vagina, tumors of cervix or vagina.)—(From Dudley's *Gynecology.*)

12. "The onset of pelvic cellulitis is usually marked by a rigor, followed by pain in one or both flanks; febrile symptoms supervene, and, as the exudation increases, troubles during micturition or defecation are experienced. These signs are of greater significance when they follow within twenty-four or thirty-six hours an abortion, delivery, or an operation on the uterus. On examining through the vagina, a hard mass will be found on one or both sides of the cervix; in many cases the hard masses are conjoined by a ring of hard tissue surrounding the neck of the uterus. When the whole extent of the ligaments is infiltrated the swelling is perceptible at the brim of the pelvis and in the hypogastrium. When suppuration occurs, the temperature, pulse, and general condition of the patient are those accompanying large collections of pus. The local signs are as follows: the previously hard masses become softer, fluctuation is detected, or the overlying skin is edematous and perhaps red. The abscess is then said to point." (Sutton and Giles' *Diseases of Women.*) The *prognosis* is favorable, if proper treatment is instituted.

PATHOLOGY.

1. *Tumors of the uterus* may be: Fibroma, fibromyoma, myofibroma, adenoma, sarcoma, carcinoma, papilloma, and syncytioma malignum.

"*Fibroids.*—These tumors are the most common of those of the uterus. Although spoken of as *fibroma*, they nearly always contain a large amount of involuntary muscle, so the term fibromyoma is the more correct. They are classified according to their situation into: mural, intramural, or interstitial, when occurring within the muscular body of the uterus; submucous, when beneath the endometrium; and superitoneal, when beneath the peritoneal covering. The tumors may be single or multiple, and their size varies from a pea to one weighing fifty pounds. The largest are the subperitoneal, as their growth is practically unlimited. The density of the tumors depends upon the amount of fibrous tissue present. They are generally encapsulated. The blood-supply is poor, so degenerations are common. These usually begin in the center of the tumor, and the most frequent form is calcification. If the tumor has been a pedunculated one, the pedicle may become twisted and necrosis set in. Fibromata may be associated with lipoma, myxoma, or sarcoma.

"*Sarcoma* of the uterus usually originates within the connective tissue between the muscle-fibers and about the vessels or occasionally from the muscle cells. It may also arise within the submucous tissue. The myometrial sarcoma is generally spindle-cell in character; is grayish-white and soft; the endometrial is commonly round celled. *Angiosarcoma* is rare, and the so-called *adenosarcoma* is probably nothing more than an inclusion of the pre-existing endometrial glands.

"*Papilloma* appears on the cervix as rather small, cauliflower-like growths, composed of connective-tissue villi covered by many layers of squamous epithelium. Venereal warts are sometimes found upon the cervix.

"*Adenomata* as such occur as polypoid projections from the mucous membrane, or as a glandular hyperplasia of the endometrium. They are benign.

"*Malignant adenoma*, or *adenocarcinoma*, usually arises in the fundus of the uterus, upon the posterior wall. It is characterized by the tendency of the glands to invade the uterine muscle and by the epithelium breaking through the basement membrane. Quite frequently the epithelium proliferates so rapidly that the acini become completely filled with cells, the glandular character is lost, and the tumor assumes a typical carcinomatous structure. Metastasis is unusual; the destruction is mainly local.

"*Carcinoma* is usually an adenocarcinoma and the progress is practically similar. There is rapid infiltration with extensive ulceration. The vaginal walls and the tissues in the neighborhood of the cervix become involved. The neighboring lymphatic nodes are frequently the seat of metastases.

"*Squamous epithelioma* of the cervix is the commonest type of malignant tumor. In many cases it probably begins as a papilloma. There is soon developed a tendency of the cells to infiltrate the surrounding tissues and to grow superficially as a cauliflower-like mass. The growth extends downward, involving the vagina; extensive ulceration, accompanied at times by severe hemorrhage, occurs, and there is an extremely foul discharge. The tumor extends in all directions, and may perforate into the bladder or rectum or into the peritoneal cavity, giving rise to fatal peritonitis.

"*Syncytioma malignum*, or *chorio-epithelioma*, is a peculiar malignant tumor developing from embryonal tissue. The greater part of the cells are supposed to be derived from the syncytium. Is a rare form of growth." (McConnell's *Manual of Pathology.*)

2. *Acute yellow atrophy of the liver.* "At a very early stage the liver may be a little enlarged, but it rapidly diminishes in size, and the disease may run a fatal course in ten to fourteen days. The liver is reduced to one-half its normal size or less, the capsule is wrinkled, the consistence tough, and the color usually yellow. The outline of the lobules is not recognizable; here and there patches of liver-cells may have escaped destruction, but for the most part they are converted into a granular and fatty detritus. Numerous hemorrhages may be found in the skin, serous and mucous membranes; the urine is almost destitute of urea but contains leucin and tyrosin. The etiology of the condition, which bears considerable resemblance to phosphorus poisoning, is unknown, but it is probably infective."—(Hewlett's *Pathology.*)

3. "*Hydrocephalus* is a condition characterized by the accumulation of an increased, and often very large, amount of serous fluid within the ventricles of the brain. This condition is sometimes spoken of as in-

ternal hydrocephalus, to distinguish it from external hydrocephalus, a collection of fluid between the brain and the dura mater. This occurs in atrophy of the brain (hydrocephalus *ex vacuo*), in advanced life, and after hemorrhages, softenings, etc.

"Internal hydrocephalus may be congenital or acquired. The congenital case may be observed at birth, when the enlarged head may interfere with parturition, or it may not become apparent until the child is some months or a year old. The condition may occur in several members of the same family. The real cause is not known, although it is likely some vice of development or a fetal meningitis obstructing the foramen of Magendie and leading to the intraventricular accumulation of fluid. The acquired cases may result from an ependymitis with marked serous exudation, a condition which Quincke believes to be angioneurotic in nature (Quincke's angioneurotic hydrocephalus); or they may be due to inflammatory (meningitis) or pressure (tumor) obstruction of the passage from the third to the fourth ventricle or of the foramen of Magendie.

"In the congenital cases and those developing in early life the head may be slightly or enormously distended. The bones of the skull are separated and the fontanelles widened; the forehead overhangs the face, the eyes are recessed, and the bones of the face seem small (ony relatively small in comparison with those of the skull). The brain is enlarged, the ventricles more or less distended, and the cortex, as a rule, correspondingly atrophied. Although rarely considerable intellectual development occurs, the mentality, as a rule, is variously impaired up to complete idiocy. Death usually occurs in childhood, but the patient may reach adult life. The cases developing in adult life can scarcely be recognized with certainty; the hydrocephalus is usually only an incident in the course of the disease to which it is due."—(Kelly's *Practice of Medicine.*)

4. *Cystocele* is a protrusion of the bladder into the anterior wall of the vagina.

Embolus is a plug of some substance blocking up a blood vessel.

Keloid is a growth occurring in scar tissue.

Lipoma is a tumor composed of fat.

Sycosis is a skin eruption involving the hair follicles, especially those of the beard.

Varicocele is a varicose condition of the veins of the spermatic cord.

Mastitis is inflammation of the breast.

Cholemia is the presence of bile in the blood.

Apoplexy is a condition resulting from hemorrhage or embolism of a cerebral vessel.

Clavus is a corn.

5. *Leukemia* is a condition in which there is a great and persistent increase in the number of white blood corpuscles. There are two varies of the disease: (1) *Splenomedullary* in which the chief changes are found in the spleen and bone marrow; and (2) *lymphatic*, in which the chief changes occur in the lymphatic glands. It is possible for leukemia to be confounded with splenic anema and Hodgkin's disease. The diagnosis is made by an examination of the blood. In Hodgkin's disease there is either no increase in the number of the leucocytes, or a very slight increase. In *anemia*, there is a marked diminution in the number of the red blood corpuscles and there is no leucocytosis. In *splenomedullary leukemia*, there is an enormous leucocytosis, and myelocytes are present. In *lymphatic leukemia*, the lymphocytes form the main part of the leucocytosis, and there are no myelocytes.

6. *Epithelioma*, or squamous-celled carcinoma, may arise on any surface covered with stratified epithelium. It usually arises in the middle-aged or elderly, but may also occur in the young. It often results from long-continued irritation, and may arise in old scars or ulcers. It may appear in one of three forms: (1) A wart-like growth with an indurated base; (2) a small circular ulcer with raised, rampart-like edges; (3) an indurated fissure. The growth extends to the deeper structures; the surface ulcerates and becomes foul from contamination with putrefactive organisms. The nearest lymphatic glands always become infected sooner or later, and a fatal termination occurs rapidly unless treatment is early and thorough. Secondary deposits, except in the glands, are rarer than in glandular carcinoma. The glands sometimes undergo cystic change, invade the skin, ulcerate, become foul, and may cause death by secondary hemorrhage from ulceration into large bloodvessels.

Microscopically, columns of cells are seen extending from the epithelium into the underlying tissues, and interlacing with one another. In some of the columns concentrically arranged masses of flattened, cornified cells occur, called 'cell nests.' The tissues immediately surrounding the growth are infiltrated with small round cells.—(*Aids to Surgery.*)

7. *Pathology of typhoid fever.*—"Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's Patches—first week.—Are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. Second week.—The surface becomes abraded; sloughs form which are often bile-stained. Third week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses. Other organs.—Spleen and liver are enlarged; heart is soft and flabby. The voluntary muscles undergo granular degeneration; in fact, similar changes to those found after death from high temperature."—(Wheeler and Jack's *Practice of Medicine.*)

8. In *mitral regurgitation*, "the most common conditions observed are more or less contraction and narrowing of the tongues of the valves, with irregular thickening and rigidity; atheroma or calcification of the segments; laceration of one or more segments; adhesion of one or more segments to the inner surface of the ventricle; thickened and stiffened, or ruptured, chordæ tendineæ, and also contraction and hardening of the *musculi papillares*. As a result of the regurgitation or leakage of the blood back into the left auricle, there is a dilatation of the auricle, followed by slight cardiac hypertrophy. Ventricular hypertrophy occurs after a time from the increased number of the cardiac contractions. If, as is eventually the case the left auricle is unable to overcome the backward flow of blood, it dilates and the lungs become congested. The right ventricle is then forced to perform more work and hypertrophies. Hypertrophy of the right ventricle is followed by that of the left ventricle. In the event of its failure to overcome the backward flow, it (right ventricle) also dilates and the tricuspid valve becomes insufficient."—(Hughes' *Practice of Medicine.*)

9. In *chronic parenchymatous nephritis* "the kidney is larger and paler than normal. The capsule strips easily and the stellate veins are injected. On section, the cortex is larger than normal and pale; the pyramids are often conspicuous by their engorgement. The pelvis shows no increase of fat. On microscopic section, the tubules are dilated, their epithelium shows fatty changes, and they contain fatty and granular casts. The epithelium lining Bowman's capsules may be proliferated, and the capillaries and epithelium of the tuft show hyaline changes. Changes in the interstitial tissue are present, such as edema and increase of fibrous tissue."—(Woodwark's *Manual of Medicine.*)

10. *Progressive changes in gonorrheal rheumatism.* "In recent cases of this disease the structures connected with one or more of the articulations are acutely inflamed. The cavity contains a variable amount of serous effusion according to its form and size; the knee, for example, being considerably distended, while the digital joints are more moderately enlarged. The various component parts are hyperemic and swollen; and the peri-articular structures full or even edematous. In more advanced cases the joints are found to contain either sero-purulent or purulent material; the cartilages may be eroded; and finally the articulations may become completely disorganized or ankylosed. The gonococcus has been found in the intra-articular effusion. The cardiac structures are very rarely affected The eye may present the ordinary appearances of catarrhal (not gonorrheal) conjunctivitis."—(Quain's *Dictionary of Medicine.*)

11. In *locomotor ataxia* the posterior columns of the spinal cord and the posterior nerve roots are involved.

The posterior columns of the spinal cord are gray and shrunken, and show considerable overgrowth of connective tissue in the columns of Goll, Burdach, and Lissauer; this process extends upwards from the lumbosacral region; the posterior nerve roots degenerate and become atrophic. The meninges over the affected parts become opaque and adherent. Some of the cranial nerves may also atrophy, notably the optic, but also the motor oculi and vagus.

The process is destructive and progressive; it is not a simple wasting, although the nerve fibers are atrophied, but it is characterized by irritation, changes in the axis cylinders, overgrowth of the connective tissue, and sometimes congestion; the spinal ganglia may be affected.

12. "The mode of formation of calculi has been much discussed. They may be produced by an excess of a sparingly soluble abnormal ingredient, such as cystine or xanthine; more frequently by the presence of uric acid in a very acid urine which favors its deposition. Sir William Roberts thus briefly states the conditions which lead to the formation of the uric-acid concretions; high acidity, poverty in salines, low pigmentation, and high percentage of uric acid. Ord suggests that albumin, mucus, blood, and epithelial threads may be the starting-point of stone. The demonstration of organisms in the center of renal calculi renders it probably that in many cases the nucleus of the stone is an agglutinated mass of bacteria."—(Osler's *Practice of Medicine.*)

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State

Aural Hematidrosis.—E. Guarnaccia and V. Sborni report a case of this condition occurring three years after an attack of Malta fever in a woman twenty-nine years of age. There was no neuropathic heredity. Instances have been reported in which there was an apparent relationship between hematidrosis and the menstrual function but in the authors' case this relationship was not manifest. Moreover there was no disease of the middle or internal ear nor any hysterical auditory phenomenon. The hemorrhagic discharge was bilateral. There were accompanying hemorrhages from the nose, larynx, and trachea. The condition lasted for three months. It is regarded as purely of hysterical origin.—*Archivio Italiano di Otologia, Rinologia, e Laringologia.*

Therapeutic Hints.

Treatment of Fatigue Dyspepsia.—Guthrie Rankin prescribes for the hyperacidity resulting from an excitable state of the gastric mucous membrane the following:

℞ Morphine hydrochloride, 1/12 gr.
Tincture of belladonna, ♏ x.
Solution of suprarenal extract (1-1000), ♏ xx.
Spirit of peppermint, ♏ xxx.

M. Sig.: To be taken in one tablespoonful of water half an hour before meals.

The hyperacidity is chemically counteracted by the following:

℞ Bismuth carbonate, xxx gr.
Magnesium carbonate, xx gr.
Sodium bicarbonate, xxx gr.

Ft. pulv., Sig.: To be taken in a wineglassful of water whenever there is heartburn.

For its tonic, antiseptic, and sedative influence the following is recommended:

℞ Extract of valerian.
Pure phenol, āā ij gr.
Strychnine, 1/40 gr.
Codeine, 1/4 gr.
Extract of rhubarb, jss gr.

Ft. capsule, Sig.: To be taken three times a day after meals.

If anemic tendencies are discernible the formula may be modified as follows:

℞ Iron glycerophosphate.
Beta naphthol, āā iij gr.
Extract of nux vomica.
Extract of cannabis indica, āā 1/4 gr.
Compound pill of galbanum (Br. Phar.), jss gr.

Ft. capsul., Sig.: To be taken three times a day after meals.—*British Medical Journal.*

Thiosinamine in the Treatment of Uterine Fibroids.—S. Artault de Vevey states that this drug has an elective action on these growths. Although it does not bring about their entire disappearance, it nevertheless effects such a marked diminution in their size as to produce a relative cure. The mode of administration is as follows: There is injected deep into the buttock, at least three times a week, 0.20 to 0.25 gram of the drug dissolved in a mixture of 10 parts of alcohol and 90 parts of glycerin.—*Bulletin Général de Thérapeutique.*

Calcium Lactate in Raynaud's Disease.—D. W. Montgomery and G. D. Culver find that calcium lactate tends to counteract the increased irritability of the blood vessels present in this disease. They prescribe the following:

℞ Calcium lactate, 50 grams.
Simple elixir, 60 grams.
Water, to make 300 grams.

M. et Sig.: Two teaspoonfuls in a little water after meals three times a day.—*Journal of Cutaneous Diseases.*

Alcohol in the Treatment of Superficial Burns.—Brestmann of Petrograd is said to have obtained good results with this method of treatment, which consists in the application to the burn of a compress wrung out in 60 per cent. alcohol. There is a prompt relief in the pain, the inflammation subsides, and healing takes place without the production of any apparent cicatrix. In deep burns alcohol is contraindicated on account of the pain.—*Bulletin Général de Thérapeutique.*

THE HUMAN PROSTATE GLAND IN YOUTH.*

BY OSWALD S. LOWSLEY, A.B., M.D.,
NEW YORK.

THIS communication deals with the anatomy of the human prostate gland in youth. The specimens utilized were obtained from routine autopsies and they have been studied in gross, microscopically and in serial section. This period includes the first and second decades of life and is particularly interesting because we are here considering the changes in a sex gland during the years of puberty. The specimens number more than one hundred and vary in age from birth to twenty years.

Serial sections of the prostate of a new born baby have been described in detail in another paper.[1] It was shown by the investigation above mentioned that at birth the gland retains its fetal characteristics in that the five foci from which it originally develops have become the five lobes of the prostate, the ducts of each group of tubules emptying into the portion of the urethra from which they originally developed. The number of tubules is somewhat less than those of younger specimens studied, but the number of branches is markedly increased. The ventral or anterior lobe at birth is very small indeed. The subcervical group of Albarran has many more tubules at birth than were noted in any of the fetal specimens. Most of these occur in the mucosa on the floor of the beginning of the urethra within the vesical sphincter. The subtrigonal glands which I have previously described in detail occur more numerously at the time of birth than previously and are simple tubular structures. The tubules of the apex group are also more numerous at birth than during previous weeks. The seminal vesicles and ejaculatory ducts, together with the utriculus prostaticus, have all been described.

It was found advisable to study serial sections of a subject who had about reached the middle of the first decade in life. Therefore, the prostate of a boy four years of age was prepared in the usual manner, mounted in celloidin, cut serially, and stained with hematoxylin and eosin. There is a slight increase in size of the gland compared with the prostate at birth. The tubules have more branches, the greater number occurring near the periphery of the organ. This fact is beautifully shown by injecting the tubules with india ink and then clearing according to the method of Spalteholtz.† It is observed that the tubules as a rule run obliquely through the muscular and elastic tissue which forms the bulk of the gland, and upon reaching the peripheral fourth, spread out in many small branches, nearly all of which point posteriorly or toward the base of the prostate and resemble very closely a wind-blown umbrella tree with the forward half of its branches removed.

The Middle Lobe.—The musculature of the tubules of the middle lobe is slightly more pronounced than that in the specimens at birth and also more pronounced than that surrounding the tubules of the lateral lobes. This is noted particularly at their ends where the capsule of the prostate is deficient and these tubules are practically uncovered by the fibrous structures which surround the remainder of the prostate. Twelve tubules make up this middle lobe, all of which grow back behind the sphincter of the bladder, some of them in immediate contact with the outermost fibers of its posterior portion, but none of them projecting within the sphincter. These tubules are clearly separated from the other portions of the gland, more so even than the case of the prostate of the new born both as regards distance and appearance.

The lateral lobes are made up of ten tubules on the left and fourteen on the right side. There is a slight growth in them compared with those of the prostate at birth. Their branches are somewhat increased in thickness and number. One small duct carries the secretion from a large number of branches which spread out over a considerable area.

The posterior lobe is made up of eleven tubules which branch rather extensively. In most parts of the gland the dividing point between the lateral and posterior lobes is well marked off by an area of tissue similar to that making up the so-called capsule of the gland. However, there are places where the partition is thin but recognizable. The ducts draining the lateral lobe tubules run toward the apex and empty into the urethra on the lateral surfaces of the verumontanum below the entrance of the ejaculatory ducts and in the prostatic furrows. Rarely does a lateral lobe tubule empty into the urethra on its lateral wall. Toward the apex of the gland the posterior lobe increases in size and in this specimen forms a considerable portion of the gland, although it is not as bulky as the lateral lobes.

Anterior Lobe.—Five small tubules make up the anterior lobe in this specimen. These tubules end in the musculature of the ventral wall and are considerably larger than the subcervical structures, although they are not nearly so extensive as the tubules of other divisions of the gland. The muscular and connective tissue envelopes are very thin. They do not extend very far from the lumen of the urethra and their ducts all enter the urethra on its ventral wall above the point where the ejaculatory ducts open.

Histologically the tubules are lined with cuboidal cells, the nuclei of which are in the center of the

*Presented at the Fourteenth Annual Meeting of the American Urological Association, Baltimore, April 15, 1915.

†Spalteholtz clearing method: Fix in formalin, dehydrate slowly in alcohol, starting in at 40 per cent. Bleach in hydrogen peroxide at 60 per cent and continue to dehydrate by increasing the strength of alcohol until absolute alcohol is reached. Clear in a mixture of 75 c.c. of oil of wintergreen and 25 c.c. of benzil benzoate.

cell. I have been unable to find any difference in the histology of the lining membranes of the various lobes of the prostate.

The small finger-formed simple tubular glands,

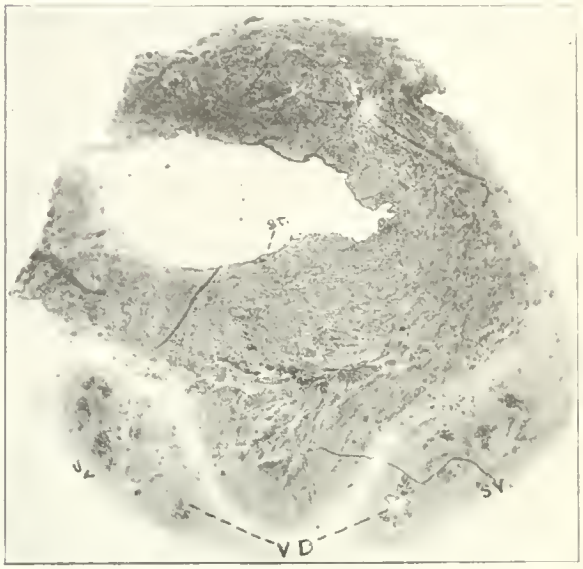

FIG. 1.—Cross-section through the midtrigonal region of a boy four years old. *ST*, Subtrigonal glands; *VD*, vasa deferentia; *SV*, seminal vesicles.

the development of which I have described previously,[2] are found in the mucosa of the trigonum vesicae at about its middle portion. There are twenty-three of these minute structures in this specimen, the uppermost of which are found as high up as the middle point of the trigone, the remainder are scattered between this point and the upper end of the vesical sphincter. There is nothing distinctive about the mucous membrane lining these structures and none of them are branched. They vary somewhat in size, but all of them are small and in no case is there muscular tissue surrounding them. The lumina are quite small and in some instances almost filled with heaped up epithelial cells. In addition to the tubules with lumina there are a number of solid epithelial evaginations which extend down to the submucosa, but in no instance do these structures extend into the submucosa.

The subcervical glands, first described by Albarran, are easily distinguishable from the subtrigonal glands and from the middle lobe of the prostate. They number thirty-three and are found in the mucosa on the floor of the urethra usually near the middle line between the vesical orifice and the upper margin of the verumontanum. They are branched and often extend for some distance into the submucosa, but grow back within the sphincter. Many of these structures at this age are simple tubular glands, but a number of them have several minute branches. Three of these structures are quite large compared with the others and, although lined with cuboidal epithelium, they are easily distinguished from prostatic tubules in that they are not surrounded by definite envelopes of muscle and connective tissue, their branches are not nearly so extensive, and the whole structure seems to be much more frail than the tubules comprising the lobes of the prostate.

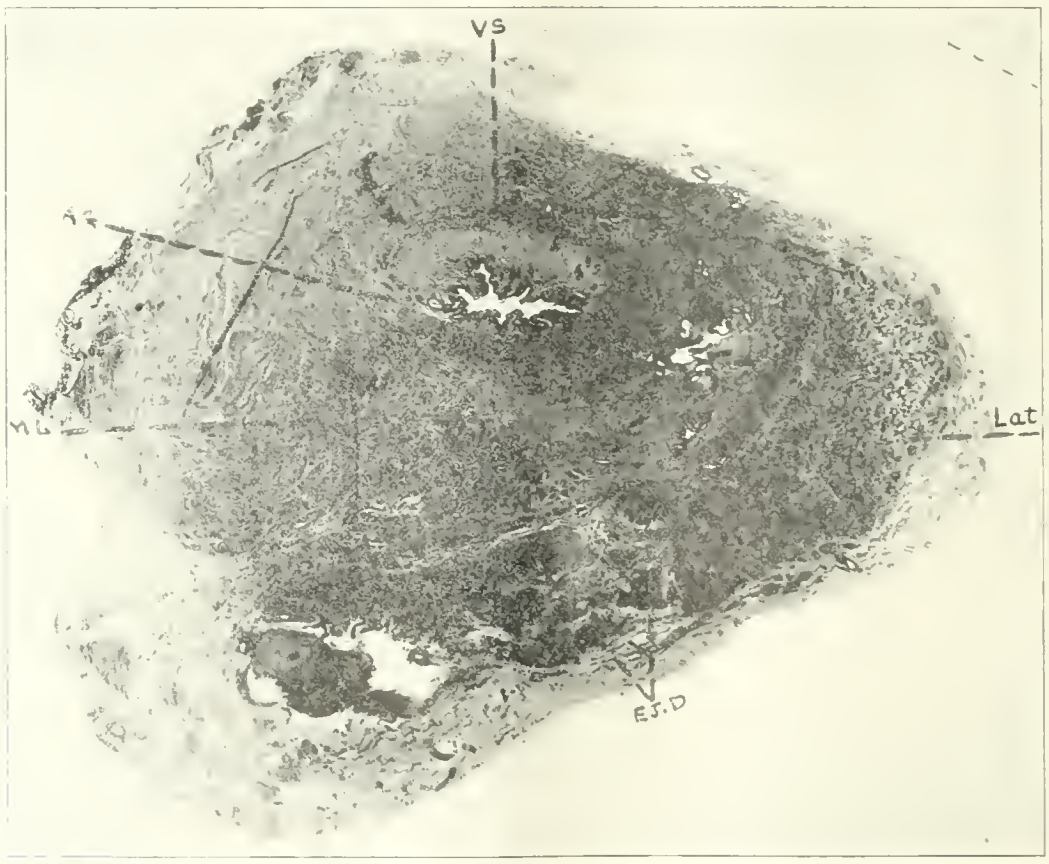

FIG. 2.—Cross-section through the vesical sphincter of a four-year-old boy; EJ.D, ejaculatory ducts; Lat, lateral lobe; ML, middle lobe; AG, Albarran's tubules; VS, vesical sphincter.

The verumontanum is formed by the ingrowth of the tissues of the ejaculatory ducts and utricle which in embryonic life have pushed up the floor of the urethra into a mound. The ejaculatory ducts

are firmly bound together and run parallel with the axis of the urethra for a short distance, finally emptying into it laterally near the summit of the verumontanum. This specimen is particularly interesting in that there is an entire absence of the utricle. The space between the ejaculatory ducts in the verumontanum usually occupied by this vestigial organ is taken up by two moderate sized tubules lined by stratified epithelium and supplied with a great many branches which empty into the urethra on the summit of the verumontanum just below the mouths of the ejaculatory ducts.

The vasa deferentia are slightly larger in size than in the specimen at birth. The seminal vesicles have the characteristic main lumen with five smaller tortuous branches as described by Pallin. The walls of the ejaculatory ducts are found to contain numerous small branched tubules lined by cuboidal epithelial cells which extend rather deeply into the musculature of their walls.†

†Dr. Morgan Vance of the Pathological Department of Bellevue Hospital has prepared serial sections of a prostate of a four year old child and allowed me to study it. In general it shows the same characteristics as the specimen described above. The middle lobe is composed of seven tubules, the right lateral lobe of eleven tubules and the left lateral lobe of twelve. The anterior lobe has four very small inconspicuous tubules while the posterior lobe is made up of eight moderately branching tubules. The posterior lobe is fairly well separated from other portions of the gland.

The subtrigonal tubules are present although quite small. The tubules of Albarran are very extensive, thirty-nine in all. Their ducts open near the midline above the verumontanum and on the verumontanum itself above the openings of the ejaculatory ducts and utricle.

Below the point where the ejaculatory ducts enter the urethra are found in this specimen a group of glands occuring upon all sides of the urethra, but chiefly on its ventral surface, which are distinctly

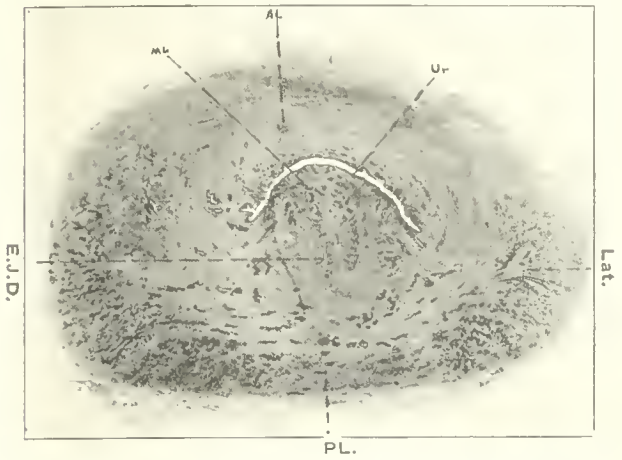

Fig. 3.—Cross-section through the upper portion of the verumontanum and prostate gland of a boy four years old. Ur, urethra; EJ.D, ejaculatory ducts; ML, middle-lobe tubules; the ducts of which are seen about to empty into the urethra; Lat, lateral-lobe tubules; PL, posterior lobe; AL, anterior-lobe tubules.

separate from the prostate. Their architecture is more fragile and they project less extensively into paraurethral tissues than do the prostatic tubules. They are not surrounded by specialized muscular tunics and their mucous membrane is composed of low columnar cells. These structures are thick-

Fig. 4.—Cross-section through the uppermost portion of the vesical sphincter of a 17-year-old lad. VO, vesical orifice; IS, internal sphincter; AG, Albarran's subcervical group of tubules; ML, middle lobe of prostate; Lat, lateral lobe of prostate; VD, vasa deferentia; SV, seminal vesicles.

The utricle is interesting in that its lower end branches and extends almost to the base of the prostate divided into nine smaller projections. At various points there are small glandular structures extending from the utricle into its muscular wall. These tubules are thickest near the orifice of the utricle. The ejaculatory ducts are also supplied with simple glandular tubules which occur quite thickly near their orifices. It is noticed that the urethral mucosa is very vascular particularly near the vesical orifice.

est directly at the apex of the prostate below which they gradually diminish in number and a short distance below the apex they practically disappear. At a number of points they extend through the submucous tissue into the investing muscular tunics, although the greater number do not extend beyond the submucosa. Some of these tubules have a number of branches; the larger number, however, are simple in their structure. There are twenty-six present in this specimen.

On account of the fact that nearly all of the specimens obtained from children were less than five years of age, it is not possible to follow the anatomy exactly during each year of the first decade. It is a strange but true fact that very few deaths occur in the hospital service in patients between the ages of five and fifteen years. The thirty-eight specimens examined show no abnormalities except one

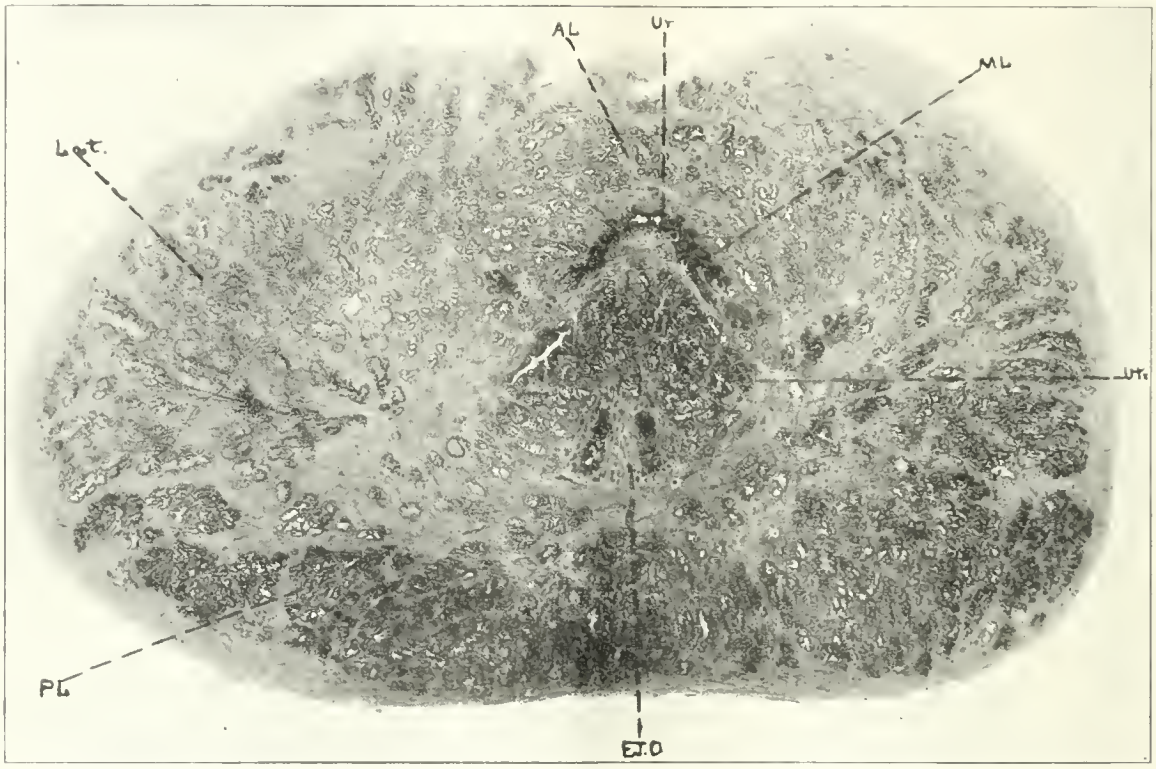

FIG. 5.—Cross-section through the level of the upper end of the verumontanum in a lad of 17 years. Ur, urethra; ML, middle-lobe tubules; Lat, lateral lobe tubules; PL, posterior-lobe tubules showing a fairly well marked partition between the lateral and posterior lobes; AL, anterior-lobe tubules; Utr, utriculus prostaticus; EJ.D, ejaculatory ducts.

case described in another communication,[1] in which there occurred an obstruction at the lower portion of the verumontanum. Surprisingly slight increase in size is made out by observation and measurement during the first decade. The average length is 1.2 cm., width 1.5 cm., thickness 0.9 cm. Distended tubules of the prostate measure at this period 0.25 mm. Thirty-three per cent of the trigonal areas show a slight but decided asymmetry. Muscular and connective tissue bundles extending between the apex of the trigonum vesicae and the upper end of the verumontanum are found in every instance. There are usually three, but there may be more and often less.

As is to be expected, there is a very great increase in the size of the prostate gland after the twelfth year. This increase seems to be even more rapid than is observed in other organs of the body. The enlargement apparently affects all the lobes to about the same degree and there is corresponding increase in the growth of inter- and intralobular connective tissue. The muscular tissue surrounding the tubular elements becomes very markedly thickened. There is no marked change in the mucosa. The alveoli are lined by the usual simple columnar epithelial cells, their inner portions often showing acidophile granules, a pseudo stratified epithelium with two rows of nuclei as pointed out by Rudinger is occassionally present. The basement membrane consists of delicate connective tissue threads as shown by Walker. The ducts are supplied with a mucous membrane composed of simple columnar cells except at their orifices, where they are replaced by transitional epithelium similar to that of the posterior urethra.

A prostate removed from a seventeen-year-old boy measures 2.28 cm. in length, 3.9 cm. in width, 1.8 cm. in thickness. It is noted that there is an increase of about 100 per cent. in the dimensions of the organ during the years of puberty. A microscopic study of the serial sections into which this specimen was cut proves to be very illuminating. Besides the great increase in size of the entire organ, there is a marked change in the elements composing it. The tubules are greatly increased in size both actually and relatively when considered with the amount of stroma present. They are distended, with secretion, in a way which is far more noticeable than in any of the younger specimens studied. The muscular tunics surrounding them are considerably increased in size and the fibers are more compactly arranged. The architecture of the tubules is discernible at any portion of their course through the gland, but it is particularly beautifully portrayed at the ends of the branches, which extend to the base of the prostate, where the component parts of the gland are not so firmly bound together as is the case elsewhere. This is most noticeable in the middle lobe region. Each branch of every tubule is contained within a heavy

muscular envelope as described by Walker.[1] It is noticeable, however, that around the branches of the tubules the circular layers are most strongly developed, while at the region of the ducts the longitudinal layer is mostly in evidence. Near their orifices the circular layer again becomes pronounced, forming a sort of sphincter.

The tubules in this specimen are arranged in five groups thereby retaining the fetal characteristics of the gland.

The middle lobe is represented by twelve tubules with numerous branches which occupy the region between the bladder, ejaculatory ducts, urethra, and the two lateral lobes. The points of entrance of the ducts of the middle lobe into the urethra are particularly widely separated from those of other portions of the structure. At most points the line of demarcation between middle and lateral lobe tubules is quite distinct, but there are points where they are only distinguishable by following from section to section and by so doing it is found that in no case do they intermingle. At the periphery the separation between middle and lateral lobes is quite marked. It is noteworthy that there is a great increase in the number of branches connected with each tubule compared with any of the younger specimens observed. The tubules of the middle lobe seem to be quite as large as those of the lateral division and no histological difference has been made out.

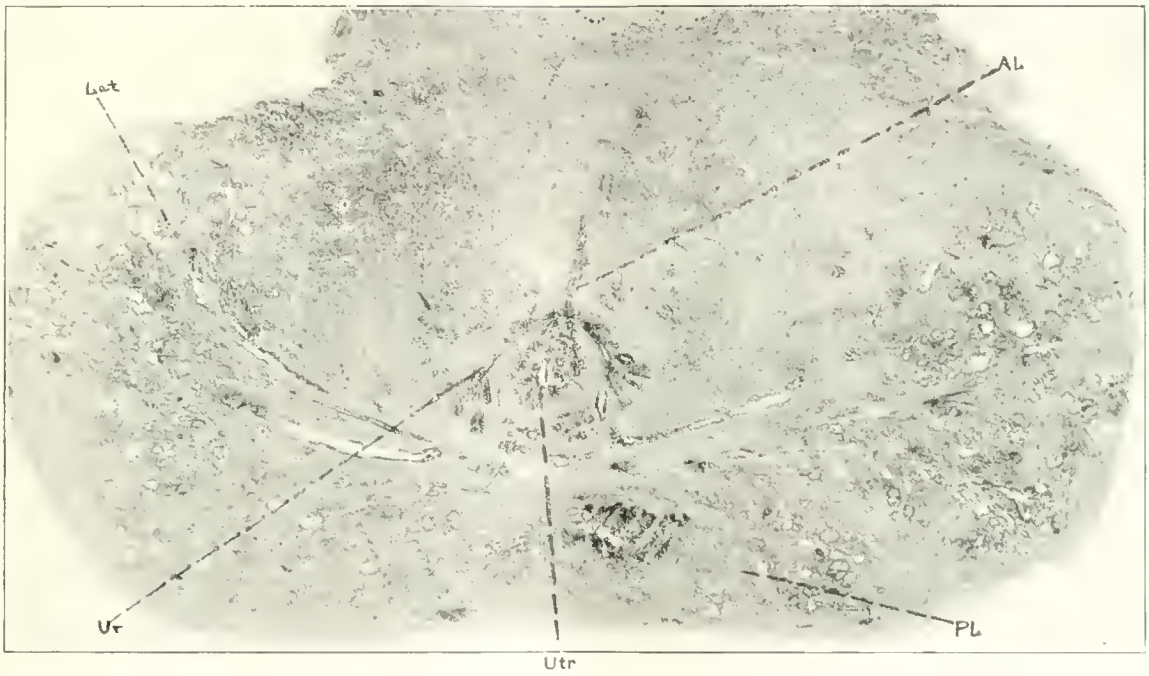

Fig. 6.—Cross-section through the level of the summit of the verumontanum in a lad of 17 years. Ur, urethra; Lat, lateral-lobe tubules; PL, posterior-lobe tubules; AL, anterior-lobe tubules, the duct of one of which is just emptying into the urethra; Utr, utriculus prostaticus surrounded by the tubular structures which empty into it and all contained within its sheath.

The lateral lobes form the largest portion of the gland as in all previous series studied. They are composed of twenty-two tubules which are large and branching and which discharge their secretion through comparatively small ducts into the urethra. Most of them empty into the prostatic furrows or on the lateral walls of the verumontanum. They extend as far toward the base of the gland as do the middle lobe tubules, but are contained within the fibrous capsule which is quite dense at this portion of the gland. Very few ducts of lateral lobe tubules enter the urethra above or bladderward from the ejaculatory duct openings. The largest and longest tubules which begin at the base enter the urethra at the level of the ejaculatory duct openings, the greater number are found below or outerward from this point. The increase in size of these tubules keeps pace with those of the middle lobe. It is not only noticed in regard to the size of the tubules, but also the number of branches. There is, however, no increase in the number of tubules. Branches of the lateral lobe tubules extend in a bladderward direction at every point except at the apex of the gland, where some of the tubules send branches forward. The muscular envelopes are thickened as has been described in discussing the middle lobe tubules. The arrangement seems to be ideal for a rapid emptying of the entire structure with considerable force. The periphery is much more thickly studded with acini than the central or paraurethral region. The ducts of the tubules proceed rather directly toward the urethra and surrounded by their thick muscular walls, pass through a dense area composed of smooth muscle and elastic tissue which is arranged in a more or less circular manner around the urethra. This structural arrangement is more pronounced in that part of the gland outerward from the openings of the ejaculatory ducts. The tubular ducts proper are comparatively short and at their proximal ends have no branches.

Posterior Lobe.—The twelve tubules which compose the posterior lobe are similar in size and appearance to those of other portions of the gland. Their ducts open into the posterior urethra on the sides of the verumontanum and occasionally on its summit outerward from the mouths of the ejaculatory ducts. This lobe is separated from the lateral lobes by a partition which is quite thick and is composed of elastic and white fibrous connective tissue with occasional smooth muscle fibers interspersed. There are some places where this tissue is thin, so that the separation between lateral and posterior lobes is not particularly marked. The amount of

prostatic tissue in the posterior lobe varies according to the location in the cross-section at which it is observed. This lobe occurs in the shape of a wedge with its base at the apex of the prostate, its apex being found posteriorly from the point where the ejaculatory ducts begin their oblique passage through the prostate. The posterior lobe, it is therefore seen, is the only portion of the gland which is palpated per rectum except in a very few instances in which the lateral lobes are greatly enlarged and may be felt on the borders of the gland. The tubules of the posterior lobe send their branches backward toward the bladder except at the very apex of the gland at which point, as is the case with some of the lateral lobe tubules, a few of the branches extend forward and become firmly imbedded in the capsule of the gland.

The anterior lobe is composed of five tubules. They are distributed along the ventral aspect of the gland from a level with the beginning of the ejaculatory ducts almost to the apex of the gland. These tubules are not as large nor do they have as many branches as do those of other lobes, but they do not entirely atrophy after puberty. In fact, from the fifth month of fetal life up to the fourth year of life they seem to be far less in size and importance than they are either before or after this period. Their lumina are distended, showing the presence of some secretion, and while a difference in size is noted it has been impossible to find any marked histological variations from the tubules of other lobes. This portion of the gland is well marked off from the other lobes.

Subtrigonal Glands.—These interesting, minute, finger-formed, simple tubules are found in the lower one-half of the trigonum vesicae near its middle portion. In this specimen there are thirty-two of these structures. They extend to the submucosa and almost never are branched. They are considerably larger in size than any of those observed in younger specimens. They do not have definite connective tissue or other differentiated envelopes surrounding them. Their general direction is oblique, the blind pouch extending toward the base of the trigone. Their appearance is insignificant, but they occupy an important position in that any considerable overgrowth would cause a serious obstruction to urinary outflow. I have found two tumors of this region in postmortem specimens and have observed three others in cystoscopic examinations. Dr. Hugh H. Young[5] saw a case which showed a peculiar hypertrophy of these tubules in which a globular structure was formed which was attached to the trigone by a pedicle. Upon attempted urination this mass would be forced into the vesical orifice, producing a complete obstruction which was easily relieved by catheterization. These tubules are lined with cells not unlike those of the bladder itself.

The subcervical glands of Albarran[6] are present in large numbers. In places their branches extend slightly within the submucosa, a condition not observed in any of the younger specimens. These tubules are much larger than those of any specimen previously described. They are, however, not nearly so large as any of the prostatic tubules. Some of the branches extend slightly into the sphincteric musculature which separates them from the tubules of the middle lobe proper. They extend as a horseshoe around the floor of the urethra from the vesical orifice to the verumontanum. Just above the upper end of the verumontanum the tubules are most profusely distributed and occur in greater numbers than at any other point. Nowhere do they extend into the tissue of the prostate gland itself.

The verumontanum shows a considerable increase in size compared to younger specimens. It is 0.45 cm. wide and 0.35 cm. high at the point where the ejaculatory ducts open into the urethra.

Utriculus Prostaticus.—This interesting vestigial organ opens on the summit of the verumontanum just below the mouths of the ejaculatory ducts. It extends backward in the summit of the verumontanum to the upper end of that protruberance running parallel with the axis of the urethra. It is lined with a mucous membrane composed of stratified epithelium, consisting of two layers of cells provided with a distinct cuticular margin upon which rests cilia. The mucosa is loose and much folded in this specimen. There are eight small glands which extend into the muscular wall of the utricle. These glands open into the utricle for the most part, but some of them open into the urethra itself on the summit of the verumontanum. They are compound tubular glands, very frail in architecture and lined by stratified epithelium.

The vasa deferentia widen out into the ampullae in the region of the seminal vesicles and there are observed a number of definite evaginations from the lumina into the solid walls which are lined with simple columnar epithelium which is occasionally pigmented.

The seminal vesicles show a very great increase in size over those of the pre-puberty specimens. The lumina of the various convoluted branches which form the vesicles are greatly enlarged and their walls are markedly thickened and more compactly arranged than in younger subjects. These organs are composed, on each side, of a main convoluted tubule with five branches extending from it, the branches being also convoluted. They are all bound quite firmly together by a white fibrous connective tissue envelope. Their lumina are lined by simple nonciliated columnar epithelium containing yellow pigment.

The ejaculatory ducts extend obliquely through the prostate in the manner hitherto described, always emptying on the lateral walls and near the summit of the verumontanum in such a way that there is a thin lamina of tissue over the mouths of the ducts, which easily occlude them, provided they are not thickened by disease, in case there is any considerable pressure in the posterior urethra. The mucosa of the ejaculatory ducts is much folded and loosely arranged. The two ducts are closely bound together and are contained within a rather firm muscular sheath which also includes the utricle in the region of the verumontanum. It is easy to see how a sudden increase of pressure within this firm envelope, as in ejaculation, would cause intense pain if the utricle were in an inflamed condition.

The apex group of glands consists of a small group of frail structures which take their origin from the urethra just at and below the apex of the prostate. Sixteen of them are observed in this specimen and most of them occupy a ventral position, although a few of them are found in the lateral walls. There are none in the posterior or dorsal wall. Their lumina are small in size and surrounded by very delicate walls. Many of them have a few branches, but some of them are simple tubules. They occur most thickly at the apex of the prostate and become fewer in number and smaller in size lower in the urethra, until they entirely disappear.

Discussion.—A most interesting feature of the anatomy of the prostate gland in youth is the enormous increase in size during the period of adolescence. Thus we see that from an average length of 1.2 cm. in the first half of the first decade the structure increases to 3.0 cm. at the end of the second decade. From a width of 1.5 cm. to 3.8 cm. and from a height of 0.9 cm. to 2.1 cm. Therefore, there is an increase of over 100 per cent. in size at this period. The size of the prostate has been a matter of interest for many years. Sir Henry Thompson,[7] one of the older writers, measured a number of prostate glands, the youngest one of which was twenty-one years of age. He found its length to be 1.3 inches, breadth 1.4 inches, and thickness 0.7 inch. Dr. Gross,[11] in his second edition on the urinary organs, made measurements of the prostate at birth and found that the width was at the base five lines, length four lines, thickness three and one-quarter lines. At four years of age he found it to be seven lines in width, six lines in length, thickness four lines. At twelve years of age width is nine and one-half lines, length eight lines, thickness four and one-half lines. At fourteen years, width nine and one-half lines, length eight lines, thickness five lines. At twenty years of age, width sixteen lines, length fifteen lines, thickness ten lines. Mr. H. P. Bell wrote on the subject[8] and found between two and four years of age the transverse diameter to be 1.24 to 1.35 cm., thickness 0.32 cm. From five to ten years transverse diameter 1.35 cm. to 1.7 cm., thickness, 0.55 cm. From ten to twelve years of age transverse diameter 1.9 cm. to 2.2 cm., thickness 0.67 cm. to 0.9 cm. From twelve to fifteen years, transverse diameter 1.9 cm. tto 2.2 cm., thickness 0.79 cm. Sir Henry Thompson measured one specimen twelve years of age and found its length to be 1 inch, breadth ¾ of an inch, thickness ⅜ of an inch. Deschamps[9] also measured a number of specimens and found in subjects from three to eight years of age the thickness to be four and one-quarter lines, width seven lines. In subjects from eight to sixteen years the thickness was five lines and width eight to ten lines.

The width is at all ages the greatest diameter of the prostate and the height the least. At the end of the second decade the prostate has assumed adult proportions and changes in normal specimens are very slight indeed. In appearance the gland seems to bulge considerably more at its base and seems to have lost the more or less rounded appearance that it possesses in childhood.

The vessels are situated chiefly on the lateral and anterior portions of the capsule, very few being found on the posterior surface. Phleboliths have not been found in any of the specimens representing the first two decades. The glands studied all show a persistence of the five lobes. Bernard Cuneo[10] says that according to Aschoff and Albarran the prostate is divided into two groups of glands, one central, which has small excretory canals and is situated under the mucosa and within the smooth sphincter, the other (the peripheral group has long excretory ducts and is called the prostate proper) that develop from the original foci in the embryo which I have already described in detail. Although the five lobes persist during the period of youth, there is not a dividing partition between middle and lateral lobes, the tubules from these divisions do not at any point intermingle and at the region where the ducts of the middle lobe tubules empty into the urethra there is wide separation of these from all similar structures.

There is a corresponding increase in the size and number of branches of each tubule of the prostate during puberty, but the number of tubules in each lobe of the gland is not increased. The increase in the number of branches occurs near the periphery of the gland and the central portion is made up of stroma and ducts of tubules. In the embryo and new born I believe that the portion of the gland occupied by glandular elements is one-fourth, but in the post-puberty period I believe that there is such a relative increase that the glandular elements occupy at least one-third of the gland and the stroma only two-thirds.

The capsule of the gland is almost entirely lacking at the middle part of the base so that the tubular branches, particularly in the middle lobe region, are held in with the general structures chiefly by the musculature of their own walls, which is very strongly developed at this point.

It has not been possible with the staining method at hand to find any histological differences in the lining membrane of the tubules making up the various lobes of the prostate. The alveoli are lined by simple columnar epithelium after puberty, the inner portion of the cells often showing acidophile granules. A pseudostratified epithelium with two rows of nuclei is occasionally present. In the younger specimens this is invariably true.

The ducts open into the posterior urethra, usually on the lateral walls of the verumontanum, in such a manner that there is a little valve-like, thin laplet of tissue over the orifice, which is easily closed by any pressure within the posterior urethra. In disease the tissues making up the orifices become indurated and stand widely open, as can be demonstrated by the posterior urethroscope, so that this wholesale valve-like action of the compressible verumontanum does not functionate. I saw a case with Dr. J. F. McCarthy of New York in which a shred of pus attached to the orifice of a prostatic tubule could be made to regurgitate into the wide open mouth of a duct at will by increasing the pressure of fluid within the posterior urethra. The greater number of prostatic ducts empty into the urethra in the immediate vicinity of the ejaculatory ducts. The middle lobe tubules all have their orifices just above the ejaculatory duct orifices, most of the posterior lobe duct orifices are just below this point, the lateral lobes have their duct orifices most thickly arranged at and below this region while the anterior lobe has its ducts, which are quite small and comparatively unimportant, all along the ventral wall of the urethra. Thus it is seen that the anatomical arrangement is perfect for making a thorough mixture of fluid expelled from the ejaculatory ducts and the prostate gland during ejaculation, thus activating the spermatozoa, as George Walker of Baltimore has shown. The ducts of the prostatic tubules are comparatively short and extend almost directly toward the verumontanum. For the most part they have their orifices on the lateral surfaces of that structure and a few in the prostatic furrows, and very few open at other portions of the urethral circumference. The posterior lobe for the most part in the specimens studied is fairly well separated from other portions of the gland by a partition made up of fibrous tissue. This partition varies in thickness and hence in distinctness, but is usually present. At the apex of the gland the lateral and posterior lobe tubules

send a few branches forward instead of posteriorly, as is always the case. This is a matter of some importance to the surgeon because during the enucleation process these forward branches protrude into a portion of the gland which is very compactly arranged so that more force is required to separate it at this point than elsewhere. The posterior lobe is the only part of the gland felt per rectum except in cases of hypertrophy of lateral lobes, in which case there may be compression of the posterior lobe and nodules are felt through it and on the lateral borders. The anterior lobe becomes very small and unimportant at about the time of birth, but in none of the cases here observed has it entirely atrophied. It is smallest at the time of birth apparently. After puberty, as in the seventeen-year-old specimen, it is quite prominent. We have other evidence that this portion of the gland may be of some consequence in the fact that in two of my series there is an hypertrophy of the anterior lobe.

The subtrigonal glands, the development of which I described in a former communication, occur in every specimen studied older than the twenty-second week of fetal life. They increase in number all during fetal life and in childhood. In the specimen of the new born there were nine of these structures, at four years of age their number increased to twenty-three and after puberty there are thirty-two. Their structural arrangement changes in size only and not in character. After puberty they are quite large, comparatively speaking. They have no differentiated tissue around them and at this time there are no branches. Their general direction is toward the base of the trigonum vesicae, but they are contained entirely within the mucosa and do not extend into the submucous structures. The epithelium is often piled up several layers thick, more or less occluding the lumina, which is in every instance small. Abnormalities of this group occasionally occur and their significance lies in the fact that they occupy a position that has the possibilities of great disturbance.

The tubules of Albarran's group increase in number during the period of youth and occupy a position within the sphincter between the vesical orifice and the upper end of the verumontanum. The anatomical arrangement here is the most important of any group of tubules in this region, considered from the standpoint of disturbance caused by a slight abnormality in their growth. They were first called attention to by Albarran, and Cuneo considered their structure to be absolutely identical with the tubules of the prostate, but I do not agree with this. Their architectural characteristics are much more slender in that their tubules are not surrounded in health by muscular or other differentiated tissue envelopes. The lumina of their tubules are smaller than are those of the prostate and while it is true that the mucosa is sometimes made up of columnar epithelial cells, these cells are smaller and inclined to be heaped up more than are those of the prostate proper. In some specimens the prevailing cell of the mucosa of this group is cuboidal. These tubules begin to develop at the fourth intrauterine month and increase slightly in size and number until birth. After birth they increase considerably in number and slightly in size. After puberty they increase enormously in size and number.

The vasa deferentia widen out into the ampule in the region of the seminal vesicles and at that point there are observed a number of definite evaginations from the lumina into the solid walls, which are lined with mucous membrane similar to that of the vasa deferentia themselves. These evaginations are not found before the period of adolescence, although a number of tubules extending into the walls of the ejaculatory ducts are found both before and after this period. The mucosa of the ejaculatory ducts in the older specimens taken from subjects in the period of youth is quite folded and loosely arranged, although the two ducts themselves are bound very tightly together by a firm muscular tissue circularly arranged.

The seminal vesicles show a corresponding increase in size during the later years of this period, their walls are markedly thickened and composed of more compactly arranged tissues. Their lumina are lined by simple nonciliated columnar epithelium containing yellow pigment.

The verumontanum is formed by the ingrowing of the ejaculatory ducts and utricle with their enveloping tissues. These structures themselves are quite firmly bound together, as has been mentioned, and most of the ducts of the prostate proper empty into the urethra on the lateral walls of the verumontanum, being more or less arranged in groups around the orifices of the ejaculatory ducts. In spite of the fact that so many compact structures traverse the verumontanum, it is a fairly compressible organ and this fact is of great importance physiologically in that any increase of pressure in the posterior urethra compresses the verumontanum and, due to the direction of the tubules of the prostate and the peculiar anatomical arrangement at their orifices, they are completely blocked off so that urine passing through the posterior urethra or pressure from other causes will permit of no regurgitation of fluid into prostatic tubules or ejaculatory ducts. It is well known that instrumentation is frequently followed by an ascending infection through the ejaculatory ducts and sometimes the prostatic tubules, more often the former. This is probably due to the fact that the ejaculatory ducts are more exposed, being near the summit of the verumontanum, and the passing of an instrument in the direction opposite to the course of these ducts causes a forcing of fluid into them.

The utriculus prostaticus is sometimes absent, as in one of the serial sections studied, in which the place usually occupied by this structure is taken up by two fairly large tubules with a great many branches which empty into the urethra on the summit of the verumontanum in the place usually occupied by the orifice of the utricle. This structure varies a great deal, its depth averages 0.4 cm. in the first decade, 0.5 cm. in the second decade. It is usually contained within the very summit of the verumontanum, but may extend to the base of the prostate. It is lined with stratified epithelium, which is loose and folded there are a number of glandular structures contained within its walls. They are compound tubular glands and also lined with stratified epithelium. There has been no instance in the specimens here studied in which an ejaculatory duct empties into the utricle. The orifice of the utricle is not protected by its position or by any tissue over it so that the long slit-like open mouth affords a very easy entrance for any infecting agent and hence gives an explanation for the frequent inflammation of the utricle. The compact arrangement of the utricle and the ejaculatory

ducts within the same envelope make it easy to understand how sudden greatly increased pressure, as in ejaculation, would cause severe pain during the act. I believe this to be the chief cause of painful ejaculation and think that this symptom is practically never due to the opening of an ejaculatory duct into the utricle. Three hundred and fifty specimens that I have studied have not shown this condition and Poroscz[16] has studied three hundred cases without finding such abnormal communication. He believes that disturbances in the sexual act are usually caused by a pathological condition of the proximal ends of the ejaculatory ducts, the musculature of which at this point he terms the sphincteric muscle.

Below the apex of the prostate a small group of glands, which I have described as the apex group, persists and increases in volume, as do the other component parts of the prostate gland. These usually begin in the lower end of the prostatic urethra and while some of them have a number of branches, for the most part in the first decade they are simple tubular structures which are quite frail as regards their architecture. Most of them occupy a ventral position, a few being found in the lateral walls, none in the posterior walls. They extend through the submucosa into the investing muscular tunics. In some instances their number increases after adolescence, as many as sixteen being observed in one specimen. Lower down in the urethra they completely disappear.

The specimens utilized in this research were obtained at the Johns Hopkins Hospital, at Bellevue Hospital, and at the New York Post Graduate Hospital. The author wishes to express his sincere thanks to Dr. Hugh H. Young of Baltimore, Dr. Charles Norris and Dr. Morgan Vance of the pathological department of Bellevue Hospital, and Dr. J. Bentley Squier, Jr., of the New York Post Graduate Hospital for their generosity and uniform courtesy.

ROENTGEN-RAY TREATMENT OF EXOPHTHALMIC GOITER.*

By C. AUGUSTUS SIMPSON, M.D.,

WASHINGTON, D. C.

ASSOCIATE DERMATOLOGIST GEORGE WASHINGTON UNIVERSITY; ASSOCIATE DERMATOLOGIST TO THE WASHINGTON ORPHAN ASYLUM; DERMATOLOGIST TO THE WASHINGTON ASYLUM HOSPITAL; DERMATOLOGIST TO THE GEORGE WASHINGTON UNIVERSITY HOSPITAL AND DISPENSARY.

THE thyroid gland in exophthalmic goiter most frequently undergoes hyperplasia, and the effects of this process are to be seen in both the stroma and parenchyme. The increased stroma or support of the gland seems to be a compensatory hyperplasia which takes place in order to meet growing demands and to supply a framework for an enlarging, growing, and ever active parenchyme. The parenchyme, active or secreting portion of the thyroid gland, in exophthalmic goiter presents several hyperplastic alterations which are more or less constant in hyperthyroidism, and which are no doubt the pathological lesions which lead indirectly to symptoms of the disease. In these cases the secreting epithelium changes from a low cubical variety to a columnar form. This apparent over-activity of the individual epithelial cells is further increased by a great and general enlargement of the epithelial cell area of not only the larger alveoli, but of the smaller ones as well. This epithelial cell increase is in many cases so marked and abundant as almost to fill the cavities of the gland, and is in marked contrast to the simple, flat epithelial cells witnessed in cases of simple goiter. The alveoli while greatly increased in number and presenting the above signs of over-activity of their lining epithelial cells, yet contain a small amount of this colloid material, and this markedly decreased colloid proves to be in most cases very weak in iodine.[1] All who have investigated the thyroid gland chemically in exophthamlic goiter agree that the percentage of iodine is generally less than normal, and it is on this percentage of the iodine content that the colloid depends for its activity. Adami[2] contends that a thick, dense colloid indicates an accumulation and storing up of this material, as witnessed in simple goiter, instead of an increased discharge of the internal secretion. MacCallum[3] has shown that in the severe cases of exophthalmic goiter the normal colloid of the gland is not only greatly decreased in quantity, but has become changed into a thin, palely staining substance which has no longer the refractive qualities of normal colloid. Lebert and F. Kocher[4] have pointed out cases of simple goiter which, having received large doses of iodine internally, developed hyperthyroidism and the classical symptoms of Graves' disease. Thus, in exophthalmic goiter there are all the evidences of highly increased secreting activity of the thyroid, yet the products of this overwork have escaped from the gland. In simple goiter no such clinical evidences of hypersecretion or over-activity of the gland are to be seen, yet the thyroid is filled with thick colloid while its percentage of iodine is very high. This leads one to suppose that the chief clinical difference in simple and exophthalmic goiter lies in the increased or decreased secretion of the highly concentrated iodized colloid from the gland. In support of such a contention one has only to mention instances where too much manipulation in the removal of the gland has produced alarming symptoms of hyperthyroidism in cases of simple goiter. Dangerous symptoms such as these occur much more

*Read before The Hippocrates Society of Washington, D. C., March 11, 1915.

frequently when operating on Graves' disease probably because of the ease with which the toxin escapes from the gland and reaches the circulation. Another reason given for such symptoms as high fever, cyanosis and difficult breathing, following thyroidectomy for exophthalmic goiter is the association of an unsuspected enlarged thymus gland. Surgeons are just beginning to appreciate the frequency with which enlarged thymus glands complicate Graves' disease. Hart,[4] Von Haberer,[5] Klose,[6] Simmonds,[7] and Nordman of Germany, Rose[8] of Paris, and Cretti[9] of Columbus, all speak of the frequency and the dangers of complication.

Simmonds found such a condition in fourteen out of eighteen cases of exophthalmic goiter, and in seven out of sixteen cases of hyperthyroidism. He believes that 75 per cent of the cases of abnormally active thyroids are associated with enlarged thymus glands. All of these men agree and insist that the enlarged thymus should be investigated and resected in order to eliminate dangerous and even fatal postoperative symptoms. Failure to do this has resulted in many deaths, both in this country and abroad. So much importance is being placed on the presence of a hyperplastic thymus that some surgeons believe that resection of this gland alone will relieve symptoms of hyperthyroidism. Von Haberer removed the thymus alone in one case with entire cure of exophthalmic goiter. The cases of reported improved Graves' disease following the ingestion of thymus tissue may throw additional light on this subject. I think all of us have seen failures following operations on exophthalmic goiters, and I am inclined to believe that the above mentioned associations have caused many of them. Cretti alone had three deaths from this cause, and in going over the histories and investigating the *x*-ray pictures of his old cases he was surprised to find a number of cases of thymic hyperplasia that he had completely overlooked. These reports certainly emphasize two important points, namely the insufficient relief surgery has given many of these patients in the past, and the increasing tediousness and danger which the complete operation of the future offers. Resection of the thymus and thyroid at one operation must increase the risks on what should be and is considered a notoriously bad operative subject.

The action of Roentgen ray on some of the ductless glands of the body has been observed for many years. While its selective effect on the testicle and ovary is now common knowledge among the profession, its atrophic action on the thyroid, thymus and pineal gland has until recently received only superficial study. While these glands may vary somewhat in their radiosensibility, any one who has investigated the literature or had the opportunity to note the effects of *x*-ray on various tissues, could not help but note the selective action of the ray on these ductless glands. Williams,[10] Campbell,[11] and Butler[12] have obtained good results with Roentgen ray in exophthalmic goiter. Freund[13] speaks of his excellent results with the same method. In five cases of Graves' disease treated by him none failed to show improvement in weight, pulse, nervousness and exophthalmus, only one tumor in the five cases treated failed to decrease to its normal size. Some of his cases were observed for one and a half years with no return of the symptoms. He reports three cases treated by Weiderman with the same excellent results except the improvement in the exophthalmus. Freund also quotes the same encouraging results by Gilmer, Schesinger, Stegman, and Schwarz. C. H. May[1] is positive that the ray lessens vascularity, improves the clinical symptoms, induces sclerosis of the capsule of the gland and better prepares the patient for the future operation. He believes that the *x*-ray, by reducing the pulse, changes a risky operation into a safe one. All of these results were obtained with what we now know to be a very crude technique. Between the lines it is easy to read that burns and vague methods kept the treatment from becoming popular among the profession. Neither the operator nor anybody else knew the amount of ray the patient was getting; hence the method was crude, inaccurate, unsatisfactory, and dangerous. The accurately measured doses of *x*-ray have worked almost as great a change in deep roentgentherapy as it has in skin cancers and ringworm. That any benefits could be had with the older methods of administration is to be wondered at when we know what a haphazard and illogical technique it was. The Sabouraud pastile method of measuring the ray allows massive doses to be given with little or no danger of producing a burn and, properly interspersed, do away with the risks of cumulative effects and burns. Now that the entire field of roentgentherapy has been placed on a scientific and sound basis it is without a doubt to play a prominent part in the future therapy of the hyperactive ductless glands. In the recent literature from France and Germany many articles appear which show what the improved technique has accomplished in the treatment of exophthalmic goiter. Ludin[14] compares his results with 208 articles on the subject, and reaches the conclusion that roentgentherapy will be the method of the future for relieving the symptoms of exophthalmic goiter. F. A. Stoner in the same article claims he had only one failure in forty-one cases, a number being benefited. Decreased nervous disturbances and slowing of the pulse were the first signs of improvement.

Some of these cases were under observation from one to four years, with no sign of returning symptoms. Ledoux of France had the same good results; he exposed the thymus gland along with the thyroid. Wagner,[15] Howell,[16] and Hollang[17] are other European physicians who give results just as favorable. Beck's cases, reported by Freund, mention two cases where the ray was applied and relieved all symptoms after an incomplete thyroidectomy. Schultz[18] in his excellent book on roentgentherapy speaks of complete atrophy of the thyroid gland being produced by the Roentgen ray, and proves by experiments that the thyroid gland is one of the most radiosensitive organs of the body. Pancost[19] lays stress on the selective action of the ray on the thyroid, especially when the gland is hyperactive as in Graves' disease. He says that one of the early and essential physiologic actions of prolonged radiation upon such a radiosensitive glandular structure, and which almost invariably precedes atrophy, is an inhibition of glandular activity. Pfahler[20] says he obtained marked improvement in 75 per cent of his patients with ophthalmic goiter. To demonstrate the fact that the Roentgen ray does cause lessening of gland activity, and even atrophy of the thyroid gland, Ludin in his article speaks of where too intense radiation of a case of exophthalmic goiter changed the condition into a typical case of myxedema. These reports are sufficient proof of the vulnerability to the *x*-ray of the hyperactive thyroid gland and class the organ with other ductless glands, testicle, and ovaries, as being unusually radiosensitive and liable to atrophy from prolonged *x*-ray exposures. My efforts in this

paper are not only to show the members of this society that a case of exophthalmic goiter may be made to undergo a lessening of its activity, or even atrophy, but to lay stress on the treatment of these cases of Graves' disease associated with hyperplastic thymus glands. That this serious complication possesses no added difficulties for the roentgen therapeutist seems evident when one reads of the experiments of Alfred Friedlander[21] of Cincinnati.

Following the reports of Heinecke and Hochsinger, Friedlander set about to learn the action of the Roentgen ray on the thymus gland. After treating and curing a number of cases of status lymphaticus by exposing the thymus gland to *x*-ray he sought to demonstrate a selective action of the ray by experiments on rabbits. His results were so successful that I would refer all those that doubt the efficiency of *x*-ray to make a study of this excellent article. Briefly, he noted that he was able to produce fibrosis of the gland with gradual disappearance of the thymus cells in every case he rayed. By increasing the length and decreasing the interval of exposures he could quicken the atrophic process up to the point where all that remained of a normal thymus was a small mass of fat and connective tissue without any glandular substances whatever. Diminution of the weight of the thymus, both absolute and relative to the body weight of the animal (as compared with the controls) was constant. The loss of weight was proportionate to the number of exposures and the length of time which elapsed between the treatment and autopsy. The general weight of the animals remained undisturbed, showing that such a loss in the thymus was not a part of a malnutrition of the animal. These experiments convinced Freidlander that the *x*-ray did have a selective action on the thymus, and supported his clinical observations on the treatment of status lymphaticus by Roentgen ray. Rachford[22] in his book on children mentions the specific effects of the ray on these hyperplastic glands, and concludes that its use will cause a decrease in the size of an enlarged thymus and control the excessive physiological action of the gland. I am at this time unable to state the frequency with which my cases of exophthalmic goiter are associated with enlarged thymus glands. In view of the recent literature on the subject and the reports of various surgeons of large experience, the percentage must be considerable. I hope to have a radiograph made of every case treated, especially those with the cardinal symptoms of exophthalmic goiter, but presenting little enlargement of the thyroid.

Cretti and Ledoux[23] have shown that such an association offers no serious obstacles to roentgentherapy, as both glands, being very radiosensitive, may be exposed at the same time. If the future proves that such a close connection exists between exophthalmic goiter and hyperplastic thymus glands it is evident that it will tremendously hinder surgical interference, while not in the least discouraging roentgentherapy. The two cases that I reported before this society last month were uncomplicated exophthalmic goiter so far as several physicians could judge without the aid of a radiograph. At least the thyroid alone was exposed, with the results that I stated. The pulse of both patients was less than eighty-five the last time they reported to me one week ago. One of the patients has been without treatment for six months with no return of the tachycardia or tremor, and a gain in weight of twenty-three pounds. The other patient had a pronounced tachycardia, the pulse at times reaching 140, considerable tremor, fever of 100 to 102, persistent headaches and sleeplessness, which she claims had been persistent for six years. She was considered a bad risk by the surgeon she consulted, and advised by him to take a rest cure. After four exposures and with no rest or relief from her hard work, her pulse is now eighty-five, her headaches have disappeared, she gets eight hours of undisturbed sleep, and she has been without fever since the first treatment, two months ago.

I have recently completed the treatments in three other cases of exophthalmic goiter with the same gratifying results. In every case that has had three or more exposures a decided slowing of the pulse, lessening of the nervousness, tremor, and exhaustion have been apparent. Along with these results the size of the tumor has decreased in most of the cases, while the patients always gain in weight, they look and feel better, and are better able to attend to their social and business duties in spite of the fact that they are kept at their regular duties and are allowed no rest cure, bromides, digitalis, or other methods or drugs to quiet them. It is very interesting to observe the slowing of the pulse in these cases. Very often this is noticeable after the second exposure notwithstanding the excitement resulting from the loud sparking and buzzing of the apparatus, the strangeness of the experience and the natural timidity of these highly nervous subjects. The pulse usually shows the first improvement forty-eight hours after the second treatment, although it is sometimes noticeable while the thyroid is being exposed, which might be partially due to the patient being at rest at this time. This continues for several days or a week, when the tachycardia again becomes troublesome. By the time the patient returns for the third treatment, two weeks later, the heart may be almost as rapid as before the treatment began. After the third or fourth exposure the effects are more lasting and are often evident at the time of the next treatment in two weeks. From this time on the improvement continues until the pulse reaches eighty, or until six bimonthly exposures are made. According to the foreign roentgenologists, if more than six full doses are necessary to show improvement the treatment should be discontinued. However, in my few cases four applications have never been necessary to benefit, but of course there must naturally be a certain percentage of cases that will not react so favorably as these. The technique is of the greatest importance and should receive the most careful study. One must remember that the patient must get large doses of ray yet not receive any Roentgen ray irritation or burns. The method that I employ is first to cover the entire area with a layer of chamois skin to protect the patient from the secondary rays given off from the aluminum filters above. Over this a heavy lead protector 3 mm. thick is placed, a hole having previously been cut large enough to allow the tumor to be palpated and located. The pastile, Hampson, is placed in a black envelope to exclude light, and this envelope rests between the edges of the opening in the lead and on the chamois and the surface to be rayed. To increase the safety, brass disks are also used; these are kept 1½ inches above the pastile and patient. The disks are 2½ in. deep and are surmounted by an aluminum filter 1 mm. thick. The filter is 1 in. below the wall of the tube, which is 7 in. in diameter. This makes a distance of 5 in. from the wall of the tube, not anode, to the patient, and 8½

in. from the anode to the patient. I make it a practice always to give between three and four points Hampson's radiometer, but never more than four points for fear of a reaction in isolated cases, although I am aware that five points of filtered ray

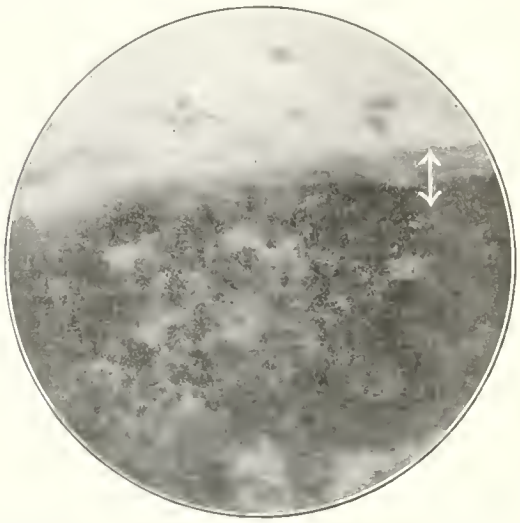

Fig. 1.—Normal delicate capsule of an untreated thymus; the line shows the normal thickness of the capsule.

could be given many cases with safety. The treatments are never given oftener than once in two weeks, which allows the skin effects of one application to wear off before another is given. I employ a medium thick filter because I wish to get rather deep action and at the same time guard against any superficial skin reactions. I do not employ the dense thick filters because I believe a hard, penetrating ray would not be the one most easily absorbed by the hyperplastic thyroid. Schultz and others have shown that to get the best results one must employ not necessarily the hardest and most penetrating ray obtainable, but the one with a hardness most easily absorbed and taken up by the lesion or gland. Poor results in treating cancers, skin lesions, and uterine fibroids may result from the employ-

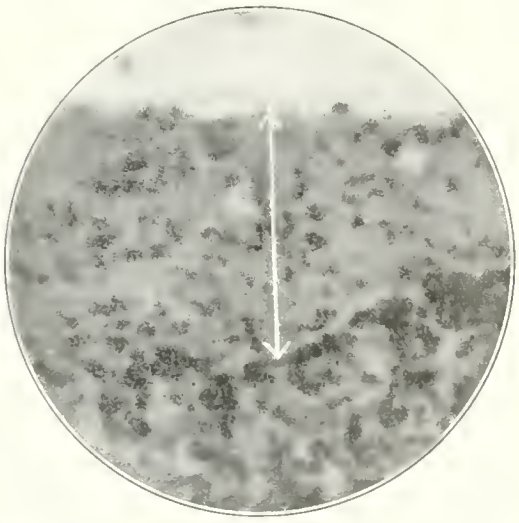

Fig. 2.—Great increase in the thickness of the capsule of a treated thymus; indicated by the line.

ment of such a hard, penetrating ray as to pass entirely through the tumor without affecting it in the least. For this reason I feel that a moderately thick filter, 1 to 1½ mm., answers our purpose better than one 3 to 5 mm. thick.

I realize that a series of five completed cases is little proof of the efficiency of Roentgen ray in exophthalmic goiter, but in a number of other cases that have had less than six exposures not one fails to show improvement in at least the pulse, weight,

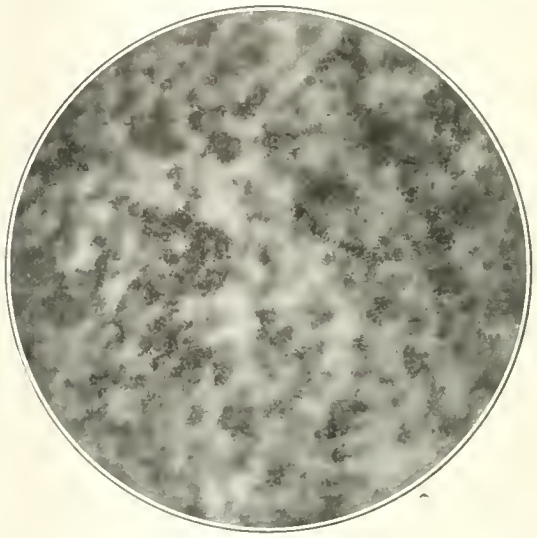

Fig. 3.—Normal cells, vessels, and trabeculæ of an untreated gland.

nervousness, and tremor. In most of the uncompleted cases the exophthalmus is still and may permanently be prominent. The latest text books on the eye contend that this symptom is the result of the thyroid poison acting on the sympathetic nerves, which in turn affects the vessels of the eye leading to their content engorgement. This continuous increased blood supply leads in the older cases to a new formation of tissue, hence the exophthalmus in such cases is permanent and explains the frequent persistence of the symptom in an otherwise satisfactory thyroidectomy. Aside from this symptom, which resection of the gland also frequently fails to relieve, I am firmly of the opinion that the great

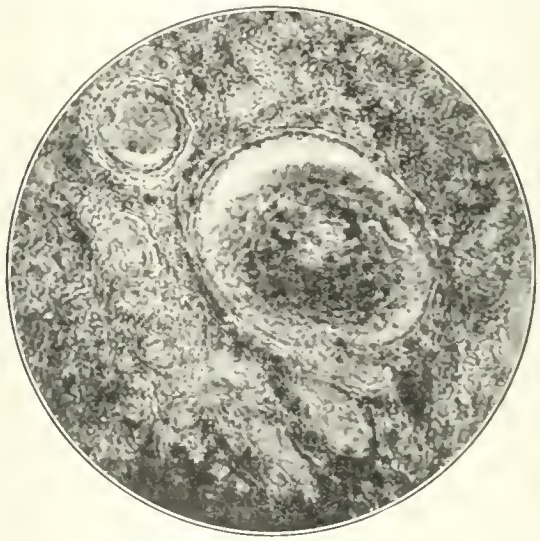

Fig. 4.—Great increase in number of blood-vessels, their intense engorgement with organizing thrombi, thickening of the trabeculæ, increase of the reticula and other signs of well advanced sclerosis.

majority of the cases of exophthalmic goiter can be relieved of all troublesome symptoms. This is not my individual view but includes the ideas of every Roentgen therapeutist of experience who has taken sufficient interest in these cases of exophthalmic

goiter to build up an accurate technique and give it a reasonable trial. Many of these patients offer risks too great for any surgeon to ignore and I believe that it is in this class of cases that the Roëntgen ray will prove most efficient. If the symptoms of the disease are of sufficient gravity the risks in that case must certainly be increased and be ample excuse for using the Roentgen ray or any other non-operative measure that will give relief. Should this method be chosen too much importance cannot be placed on the experience of the *x*-ray operator. Past performances have proved that the mere ownership of a machine does not entitle one to do such technical work, nor does it prove that one who takes and interprets *x*-ray pictures fairly well is competent to undertake it. It is necessary for the future general practitioner to know enough about roentgentherapy to choose the competent men of his community, not only in order to get the best results, but to prevent one of the most useful therapeutic methods we have from being discredited and condemned.

Conclusions.—1. Many cases of exophthalmic goiter are associated with enlarged thymus glands and this association often causes serious postoperative symptoms and even death.

2. While such an association will seriously complicate and prolong a surgical operation, it offers no such added difficulties for the Roentgen therapeutist.

3. Not only such ductless glands as the ovaries and testicles but also the enlarged thyroid and thymus glands as well are very sensitive and may be atrophied by the Roentgen ray.

4. This theory has been amply proved by laboratory experiments and clinical results in many cases of hyperactivity of the thymus gland seen in cases of status lymphaticus and hyperactivity of the thyroid gland—exophthalmic goiter.

5. If these cases of status lymphaticus and exophthalmic goiter will give the Roentgen ray a fair and impartial trial the majority of them will be relieved of all troublesome symptoms and make unnecessary a disfiguring, dangerous and often futile operation.

6. The above findings are not entirely my own hastily formed ideas but include the results of several hundred cases of exophthalmic goiters that have been successfully treated by the Roentgen ray, the literature of which is open to all who may care to investigate it.

April 1, 1915.—Since this report was read I have completed the treatment in five additional cases of Graves' disease. In every case the patients gained in weight, the nervousness has very much improved, they sleep better, the tumors have decreased in size, the tremor disappears and the pulse in every case but one was brought below 85. Some had been as high as 160. In this one exception a radiograph showed the patient had an active tuberculous lesion in one lung associated with an evening elevation of temperature of 102 deg. and a pulse that failed to go below 112. The goiter in this case has greatly decreased in size, the general nervousness has improved, while the tremor is no longer noticeable.

Action of Roentgen Rays on the Thymus.—To demonstrate the action of the Roentgen ray on the thymus gland I took two guinea pigs of the same weight and age for experimental purposes. The post mortem findings in these two pigs were compared to those on a normal untreated control pig of approximately the same age and size. There was a great difference in the size and appearance of the treated glands when compared to the untreated gland. To the unaided eye the amount of of thymic tissue was little more than half of that found in the untreated case. Microscopically the findings were even more marked and could be divided into a capsular and an interstitial hyperplasia, both increasing to a marked degree, leading to a distinct sclerosis and a reduction in the amount of the gland tissue proper. The capsule of the treated glands was in places increased to six times the thickness of those untreated, as the pictures show. Below the capsule the findings were even more interesting. The veins, arteries and capillaries were widely engorged with thrombi and organizing blood clot. The walls of the blood vessels were thickened. The thrombi in places were undergoing hyaline degeneration and showed in some locations the conversion of hemoglobin into hemosiderin, proving ante mortem formation of the clot, all pointing to the future organization of the vessel contents leading to an additional sclerosis of the gland. In addition to this, there was a decided thickening of the delicate trabeculæ and a great increase in the reticula taking place at the expense of the thymic cells.

Technique of Roentgen Ray Exposures.—The treated pigs were each given 3 points Hampson's radiometer every other day until 12 points Hampson or 3 erythematous doses were given. This was applied over the upper thorax and neck of the pig, the ray was filtered through 1 mm. of aluminum, and two layers of chamois were employed to protect the skin from secondary rays. The pastiles were covered with black paper and placed on the exposed surface and under the chamois. In this case the two pigs received an unusual amount of hard ray in a very short time, eight days. Under ordinary circumstances this amount of ray is almost three times the amount recommended for human beings where skin irritation is to be avoided. An ordinary *x*-ray tube was employed, a 1 KW. transformer with a 4-inch spark gap being used to excite it. In addition to these experiments, I have exposed the thymus of two rabbits to the Roentgen ray to note the effects when compared with a normal control and also to see the effect such raying would have on the blood picture. According to Lampe and Liesegang the removal of the thymus is followed by a great fall in the lymphocyte count. Garrés and Halstead have seen a great reduction in the number of lymphocytes following resection of the thymus. Rachford has seen rapid disappearance of a lymphocytosis accompanying status lymphaticus when the thymus was exposed to the Roentgen ray. Of the two rabbits that I exposed to the ray, one was rayed every day for eight days, getting in all, six erythematous doses of ray or 24 points Hampson radiometer through 1 mm. of aluminum and using a Coolidge tube excited by a 16-inch coil. The white cell count in this rabbit before treatment began was, polymorph onuclears 39, lymphocytes 60, and mononuclear 1. After eight days of intense treatment with a filtered ray the count was polymorphonuclear 40 and lymphocytes 60. At this time, not having had the gland sectioned, I am unable to state the amount of thymic destruction caused by giving so much ray to the thymus, but compared with the changes in the case of the pig which received only one-half the amount, it must have been considerable, certainly enough to cause some change in the lymphocyte count, which how-

ever did not take place. For this reason I am compelled to think that the enormous fall in the number of lymphocytes following destruction of thymic tissue as reported by the above investigators must be explained in some other way.

CEREBELLAR SYMPTOMATOLOGY.*

By MALCOLM S. WOODBURY, M.D.,

CLIFTON SPRINGS, N. Y.

It is universally true in regard to symptoms associated with lesions of the nervous system that the pathological anatomy and physiology of the affected areas furnish a ready explanation for the symptoms which are encountered, the only limitation being that our physiological and anatomical knowledge is very incomplete.

The cerebellum may be roughly divided into two lateral lobes and a central lobe or vermis. The cerebellum is not in the usual acceptation of the term either truly motor or truly sensory in function. It receives impressions from afferent tracts and transmits impressions to certain efferent tracts. The following anatomical reminders will serve to recall the more essential elements concerned in connecting the cerebellum with other structures.

The component fibers of the posterior spinal nerve roots may be subdivided into several different groups varying in destination and function; only one of these groups concerns us at the present moment. The fibers of this group enter the posterior portion of the cord and terminate in arborizations around the cells of Clarke's column. Thence new neurones extend by way of the direct cerebellar tract and Gowers' tract to the cerebellum—the direct cerebellar tract by way of the inferior peduncle, Gowers' tract by way of the superior peduncle. Both these tracts are homolateral, though some writers hold that there may perhaps be contributing fibers to Gowers' tract from the contralateral side.

These tracts represent the principal afferent fibers from the cord to the cerebellum, and furnish the direct nervous connection between muscles and joints and the cerebellum, to which they convey joint and muscle impressions.

There are two principal efferent tracts which leave the cerebellum, one being the vestibulospinal tract, and the other the rubrospinal tract. Both are physiologically essentially homolateral (though the latter becomes so only after crossing to the red nucleus of the opposite side and then recrossing to the side of its origin), and both convey stimuli from the cerebellum to joints and muscles by way of the anterior spinal nerve roots. Recognition of these facts reveals the reflex mechanism which permits cerebellar muscle control.

There is also a connection between the cerebellum and the oculomotor nerves by way of a group of fibers which is known as the posterior longitudinal bundle. Furthermore, there is a connection between the internal ear and the cerebellum by way of the vestibular nerve, the vestibular nucleus, Deiter's nucleus, thence to the vermis.

The cerebellum, then, is a reflex apparatus in close connection with the spinal cord. It is a modifier of influences, rather than an originator. It is closely connected also with the semicircular canals and with the eye muscles, and, furthermore, there are fibers connecting the frontal and temporal cerebral regions with the cerebellum.

While it is not an originator of motion, it in a way presides over motion and provides for cooperation of muscle groups (synergia), and graduates the strength of nerve impulses (eumetria). It regulates the inervation of the trunk, limb, and eye muscles in such a manner as to secure continuous and harmonious maintenance of equilibrium (Bing).

The question of definite cerebellar localization has been much discussed. Ferrier maintains that the various segments, particularly of the vermis, have specific function. Rothmann and the Italian neurologists support the theory of definite cerebellar localization. Horsley and the English school have not been able to confirm these claims. Balk, a Dutch comparative anatomist, has worked out a rather elaborate scheme of localization. He appears, at least, to have shown that all areas in the cerebellum are not of equal consequence; for example, he points out the interesting fact that the spinocerebellar tracts end in the vermis, and that in animals requiring a high degree of skill in the maintenance of balance the vermis is highly developed.

The chief and more characteristic symptoms of cerebellar disease may be grouped under four heads: (1) Ataxia (incoordination); (2) hypotonia (reduced muscle tone); (3) astasia (tremulousness); (4) asthenia.

Asthenia is an inconstant general symptom. Astasia or tremulousness occurs only in unsupported parts on the affected side—it is not a true tremor but rather a tremulous unrest. The symptom of chief importance is *ataxia*, and without ataxia a diagnosis of cerebellar disease is not justified.

Cerebellar ataxia affects chiefly the larger and more complicated movements. Simple movements, such as flexion, extension, abduction, or adduction may be correctly executed. It is the lack of "team work" of the muscle groups, *i.e.* the lack of synergia that is really characteristic.

*Read before the Ontario County Medical Society, April 9, 1915.

Synergia implies the proper action of opposing muscle groups and of other groups contributing to the performance of movement. Thus, to flex the fingers to the best advantage the wrists must not flex. This cooperation of muscles is imperfect in cerebellar disease. As a result of this, inability to maintain the balance is frequently present.

In order to test synergia, Babinski has the patient stand well balanced and suddenly throw back the head. In the event of impaired synergia the patient loses his balance. Another test is rapid alternate pronation and supination of the forearms, or similar tests involving the smaller movements. In case of unilateral cerebellar disease there is marked impairment in the ability to perform these movements on the affected side, a symptom which Babinski calls adiadochokinesia. Dysmetria or the failure to judge distances is another evidence of incoordination. For example, a cerebellar patient reaching for an object will frequently overdo the movements necessary in obtaining it.

Cerebellar ataxia is not affected by closing the eyes. The more complex a movement is the more likely is it to bring out the ataxia. The typical gait of the cerebellar patient is the "drunken stagger".

In unilateral disease, deviation in walking is toward the affected side. The patient may complain of a sense of being dragged toward the side of the lesion; accordingly, in starting to walk he sets himself with the shoulder of the affected side forward to counteract this tendency. If the patient is on his hands and knees he may present the "corkscrew" symptom. Thus, if the head represents the handle of the corkscrew, a left-sided cerebellar lesion produces the attitude of an ingoing corkscrew. That is the left buttock will be lower than the right.

Certain other tests have been elaborated, as, for example, Bárány's rotation test. Under normal conditions, when the patient is rotated rapidly to the left, if he tries to point at an object when the rotation ceases he will point to the left of it and have nystagmus to the right. If he has right cerebellar disease he will point more directly at the object and does not have nystagmus. Bárány's test of producing nystagmus by injecting cool water into the external auditory canal is of considerable value. In case of involvement along the vestibular tract the nystagmus does not occur as in the normal subject. Weisenberg has recently effectively emphasized the value of these tests when properly applied, and has well urged their routine use in suspicious cases.

Pure cerebellar disease causes no cranial nerve symptoms. Neither does it cause a disturbance in reflexes. However, pressure symptoms, producing cranial nerve symptoms and reflex disturbances, may result in cases of cerebellar disease, as in diseases affecting any other intracranial structure.

Hypotonus is a rather frequent symptom in cerebellar disease, inasmuch as the spinocerebellar and cerebellospinal tracts are concerned not only in the regulation of muscle movements, but also in the maintenance of muscle tone. Whereas hypotonus in spinal disease is accompanied by reduced reflexes, this is not true in pure cerebellar hypnotonus. It is true, however, that cerebellar growths may produce pressure in such a way that there is a marked increase in the pressure of the cerebrospinal fluid so that the posterior nerve roots may be disturbed and reflexes may be diminished. Hypotonus involves chiefly the body and extremities on the same side as the cerebellar lesion, though it may be to some extent bilateral, especially in conditions involving the vermis.

While these two symptoms, ataxia and hypotonia, are the most characteristic cerebellar symptoms, even they are not pathognomonic, for it is evident that lesions affecting the tracts leading to or from the cerebellum may produce similar symptoms—as, for example, Friedreich's disease.

Next in symptomatic importance is vertigo, which in type is practically identical with labyrinthine vertigo. It is rotary, giving rise to sensations of rotation between the patient and external objects. The vertigo may be so troublesome as to cause vomiting. The explanation of the vertigo would seem to be that the vestibular nerve is involved either by disease or by pressure, so that the information received by the cerebellum from the labyrinth does not correspond with the information received from the muscles and joints of the trunk and extremities; these paradoxical reports produce confusion as to the true location of the head and body in space, and vertigo results.

Rotary vertigo then may occur either in affections of the labyrinth, affections of the vestibular nerve, vestibular nucleus or in intracerebellar disease. In case of intracerebellar lesions the tendency is for rotation of self and of external objects toward the side of the lesion.

If the labyrinth or vestibular nerve is involved, as in extracerebellar disease, the tendency is for rotation of self toward the side of lesion, and rotation of external objects in the opposite direction.

A fourth common cerebellar symptom is nystagmus. This is usually slow, strong, of wide range, and most marked toward the side of the lesion, and increased by eye movements toward the side of the lesion. Divergence toward the well side produces diminution in the range of the nystagmus and makes it more rapid. The explanation of eye symptoms in cerebellar disease is furnished by the connection between the cerebellum and the occulomotor nuclei by way of the posterior longitudinal bundle, as previously stated.

Moderate speech defects may occur.

Occasionally, when the cerebellar peduncles are involved, one observes forced movements toward one side or the other, such as forced rotation of the head or trunk.

In conclusion, it should be stated that several symptoms which are common to intracranial lesions are frequently present in cases of cerebellar disease. For example, persistent headache, sensitiveness to pressure or to percussion over the affected area, persistent nausea and vomiting, and choked disc.

The following case history illustrates a number of the points in the symptomatology of cerebellar lesions. The patient was seen with Dr. Brotherhood.

CASE 16061.—Woman, married, aged 63. Family and personal history and general physical examination may be omitted, as the points of particular interest appear in the neurological examination and the patient's general condition was relatively good. Patient was well up to two years before her admission. At about that time she began to be affected with a moderate degree of dizziness. This had continued up to the time of admission and had been gradually increasing. She described the vertigo as undulatory and rotary, both herself and eternal objects having tendency to rotate to the right. Dizziness was not constant but was produced by any change of position. She was more likely to be free from it when lying down than when sitting or standing, though it had been present at times even when she was lying down. The dizziness was at first es-

pecially pronounced in the morning and particularly when the patient was going upstairs.

After the onset of the dizziness, there had been more or less headache. Shortly before admission the headache had appeared about twice each week or even more frequently. It was at times very severe, affecting particularly the back part of the head, continuing usually not more than fifteen minutes, but at times lasting considerably longer than this. An acute exacerbation of the headache might be produced by turning the head, by increased intraabdominal pressure when the bowels were moved with effort, by coughing, sneezing, or exertion.

Three months previous to admission, after going upstairs, she "gave out," did not completely lose consciousness but fell. She succeeded in getting on to a bed. She stated that the fall was due entirely to dizziness. Her husband stated that about four months previous to admission, he noticed a little thickness in speech which continued up to the time of admission, without any particular variation.

For two months previous to admission, the patient was not able to walk alone and when walking with support was very unsteady, the right side appearing to be the weaker, and the stagger, which she said was like that of a drunken individual, was more pronounced toward the right side. For several months previous to admission, she has had considerable nausea which was more marked at the time of her headache, but occurred occasionally without headache. She never vomited. Previous to two years before admission she never had suffered from nausea.

Neurological examination: Gait—"drunken stagger," with a tendency to fall more particularly to the right. Patient unable to walk alone. Romberg showed no difference in the ataxia with eyes open or closed. Pupils reacted actively to light and accommodation. Eye movements were fairly free in all directions. Marked lateral nystagmus about equal in the two directions, perhaps slightly more marked toward the right. The left disc was apparently normal. Retina showed moderate tortuosity of vessels. No atrophy, no swelling of the disc. The right showed decidedly tortuous vessels and moderate but distinct swelling of the disc and blurring of its upper margin. This, however, was not sufficient to be regarded as a definite choke.

No evidence of cranial nerve involvement (except the nystagmus). Moderate incoordination of the arms (finger-nose test). Marked incoordination of the right leg. Moderate adiadochokinesia of the right forearm. Touch, pain, and temperature sense normal. Sense of passive motion notably impaired in the right leg, a difference of 45° not being appreciated, whereas on the other side very slight changes were noted by the patient. Sense of position definitely impaired on the left, a change of position of 45° not being recognized; sense of position normal in the right leg. Sense of vibration not impaired. Sense of spacial discrimination showed a very wide threshold about equal on the two sides.

Deep reflexes of the arms active. Knee kicks and ankle jerks active and equal. No ankle clonus, no patella clonus. No Oppenheim, no Gordon, no Babinski. Abdominal reflexes not made out perhaps because the abdominal musculature was flabby. No definite weakness in the legs or arms.

Impression: The ataxia was definitely of the cerebellar type. The fact that it came on together with other suggestive symptoms and had been increasing, raised the suspicion of cerebellar lesion. Dizziness occurring two years previous to admission and gradually increasing, headache appearing at about the same time, troublesome nausea, nystagmus, adiadochokinesia of the right arm, swelling of the right disc, incoordination of the right arm and leg all suggested cerebellar disease.

The absence of cranial nerve involvement, especially the fact that the auditory nerve had escaped, suggested that the growth was probably intracerebellar. The involvement of the right arm and leg, together with the character of the nystagmus, suggested that the growth was right-sided. The slow progress of the disease made it seem likely that the patient was suffering from a glioma. It was thought that there might perhaps have been a small hemorrhage into the growth at the time the patient fell after going upstairs.

Diagnosis: Right intracerebellar glioma.

The patient was referred to Dr. Harvey Cushing. The diagnosis was confirmed at operation, and the patient was much improved when last heard from.

A VOLUMETRIC DETERMINATION OF THE SULPHATES IN THE URINE.*

By ALWYN KNAUER, M.D.,
BONN, GERMANY,
AND
BENJAMIN HOROWITZ, PH.D.
NEW YORK.

(From the Physiological Laboratory of Fordham University Medical School.)

THE method herein outlined is a volumetric one and depends upon the so-called Mulder's end point, the principle of which is well known to those familiar with the Habel-Fernholtz chloride determination.

Gay-Lussac in 1832 (Instruction sur l'Essai des matières d'argent par la voie humide, Paris) and Mulder in 1859 (Die Silberprobiermethoden, Leipsig, XIX, 311; *Chem. News,* IV. 99, 125, 137, 204, 231, 297, 321 (1861), V, 2, 1862), both noticed that AgCl was sufficiently soluble to introduce an appreciable error in the determination of Ag or chlorine by precipitation as AgCl. Mulder records that when equivalent quantities of $AgNO_3$ and NaCl are mixed the filtrate will still give a cloudiness either with $AgNO_3$ or NaCl. Whereas Mulder's experimental findings have withstood the test of time, and have indeed been successfully applied by Habel-Fernholtz (*Pflügers Archiv f.d. ges. Physiol,* 23, 85, 1880), his explanations, in the light of present-day physico-chemical conceptions, are valueless.

Principle of the sulphate determination.—When a soluble sulphate is added to a soluble Ba salt, $BaSO_4$ is precipitated:

$$BaCl_2 + K_2SO_4 = BaSO_4 + 2KCl.$$

This is more correctly shown in the following:

$$\left.\begin{matrix} K_2SO_4 \rightleftarrows 2K^{\cdot} + SO_4'' \\ BaCl_2 \rightleftarrows Ba^{\cdot\cdot} + 2Cl' \end{matrix}\right\} \rightleftarrows BaSO_4 \text{ (dissolved)} \rightleftarrows BaSO_4 \text{ (solid)}$$

This takes into consideration the ionization of the salts, and the separation of the non-ionizable product. It also emphasizes the important fact that no matter how insoluble a substance may be, it is soluble to some extent, and part of the soluble portion will itself be ionized:

$$BaSO_4 \text{ (dissolved)} \rightleftarrows Ba^{\cdot\cdot} + SO_4'' \qquad (1)$$

The law of mass action applied to (1) gives

$$[Ba^{\cdot\cdot}] \cdot [SO_4''] = [BaSO_4] \cdot K \qquad (2)$$

Where $[Ba^{\cdot\cdot}]$ = conc. of Ba ions, etc.

But since we are here dealing with a highly insoluble substance, the soluble part must form a saturated solution, the concentration of which is dependent only on temperature. Hence $[BaSO_4]$ is constant (call it k). Substituting in (2) we have

$$[Ba^{\cdot\cdot}] \cdot [SO_4''] = k \cdot K = K' \qquad (3)$$

which means that in a saturated solution the product of the concentrations of the Ba ions and SO_4 ions remains constant, and is equivalent to K′ (the Ostwald solubility product).

It is evident that the addition of either $BaCl_2$, or K_2SO_4 would upset the equilibrium in (3) by introducing more Ba ions or SO_4 ions. The adjustment is brought about by a further precipitation of $BaSO_4$.

In a highly insoluble salt such as $BaSO_4$, where the solubility product is so small, a small excess either of $BaCl_2$ or K_2SO_4 would be more than enough to go beyond the end point, which is reached when equal cloudiness is obtained with the same quantity of either of the salts.

Method: Solutions required

(A) $BaCl_2$, 1 c.c. = 0.005 g H_2SO_4

(B) K_2SO_4, 1 c.c. = 1 c.c. of solution (A)

A.—*Total (inorganic and ethereal) sulphates.*—

The preliminary procedure is based on Folin's well-known method. Fifty c.c. urine and 5 c.c. HCl (S. G. 1.2) are poured into an Erlenmeyer flask, and the mixture boiled for about 10 minutes. $BaCl_2$ (solution (A)—usually 10-15 c.c.) is now added, and the mixture boiled for 3 to 4 minutes further. Three small test tubes of uniform bore and scrupulously clean are now placed side by side in a test tube rack, and labelled 1, 2 and 3. Small portions (not more than 1 c.c.) of the solution are filtered into each, using a very small funnel and a very small filter paper for the purpose. (1) is kept as a control. to (2) three drops of $BaCl_2$ and to (3) three drops of K_2SO_4 are added. If not enough $BaCl_2$ has been added then (2) will appear cloudy; if the $BaCl_2$ is in excess, then the cloudiness will make its appearance in (3). In either case the contents of the test tubes are carefully poured back into the main solution, the test tubes and filter being thoroughly rinsed with distilled water, and 1 c.c. of $BaCl_2$ or K_2SO_4, depending upon which is in excess, is now added. The tests are once again repeated. If in the first trial test tube (2) gave a cloudiness, and after the addition of another c.c. of $BaCl_2$, it still continues to give a cloudiness, whereas (3) is clear or far less cloudy than (2) this means that there is an excess of SO_4 ions, and therefore more $BaCl_2$ is added. If the further addition of $BaCl_2$ causes the reverse to take place—namely, clear or slightly cloudy in (2) and decidedly cloudy in (3)—then there is an excess of Ba ions, and therefore more K_2SO_4 is added. It is evident that if at a given point the reverse phenomenon is observed to that which we had with 1 c.c. less, then the end point must lie somewhere between these two. If the determination need be approximate only, then the average is taken. If not, further trials, taking tenths of a c.c., are made, until a point is reached where 3 drops each of $BaCl_2$ and K_2SO_4 added to (2) and (3) give precisely the same cloudiness. To confirm this end point, another sample of urine is taken, the number of c.c. of $BaCl_2$ used in the first filtration are run in immediately, and the test repeated.

B.—*Inorganic Sulphate.*—The procedure is analogous to the above, except that acetic is substituted for hydrochloric acid, and the solution is *not heated.*

A — B = *ethereal sulphates.*

C.—*Neutral Sulphur.*—Here 50 c.c. urine are treated with 5 grams of KNO_3 and 7 grams of Na_2CO_3. The mixture is evaporated and then heated till all the carbonaceous mass has been oxidized. The residue is dissolved in water, the solution poured into an Erlenmeyer flask, neutralized with HCl, and 5 c.c. of HCl (S.G. 1.2) is added. From here follow A. This will give total sulphur. If we now subtract the total sulphates (obtained in A) from this, the result will be neutral sulphur.

Example.—Fifty cubic centimeters of urine were treated as described, and 15 c.c. of the $BaCl_2$ were added. The test showed incomplete precipitation. Successive additions of $BaCl_2$, 1 c.c. at the time were made, tests being performed after each such addition. After 21 c.c. had been added a test portion still showed a cloudiness with $BaCl_2$, but the addition of a further cubic centimeter gave a cloudiness with K_2SO_4, but none with $BaCl_2$. Hence we knew the point to lie between 21 and 22 c.c. One-half cubic centimeter of K_2SO_4 were now added. Here a cloudiness was obtained with $BaCl_2$, but none with K_2SO_4. This meant that this point must lie between 21.5 and 22 c.c. The further addition of 0.2 c.c. of $BaCl_2$ gave the end point (equal cloudiness with both).

Amount of $BaCl_2$ used = 23.7 c.c.
Amount of K_2SO_4 used = 2.0 c.c.

Actual amount of $BaCl_2$ needed = 21.7 c.c.
Since 1 c.c. = 0.005 g H_2SO_4
21.7 c.c. = 0.005×21.7 grams.
But this is in 50 c.c. urine. Hence in
100 c.c. = $0.005 \times 21.7 \times 2 = 0.217$ grams.

(The advantage of making a solution where 1 c.c. = 0.005 g is apparent. In order to get the percentage of sulphates, the burette reading is taken, and the decimal point moved two places to the left.)

The amount of urine collected in 24 hours = 1600 c.c. Hence the amount of sulphates in the 24 hours sample = $0.217 \times 16 = 3.47$ grams. (Calculated as H_2SO_4.)

In conclusion, it may be added that in point of accuracy this method compares most favorably with the usual gravimetric method. Once the procedure is mastered a determination can be made in 15 to 20 minutes. To the clinician, therefore, in particular, the time-saving factor, as well as the simplicity of the method, should prove of value.

PAIN AND ITS SIGNIFICANCE.*

By J. H. DEMPSTER, A.B., M.D.,
DETROIT, MICH.

THERE is no other presenting symptom which brings patients to the physician more frequently than pain. It has been estimated that more than 90 per cent. of all diseases either begin with it, or have it as a prominent symptom some time during their course. Pain has been regarded as the most universal symptom of disease; it may range from a comparatively mild discomfort to a sensation of the most agonizing kind. An accurate diagnosis frequently depends upon its proper interpretation. It is the main subjective symptom in its various manifestations which we as physicians endeavor to relieve. Cabot, in his work on "Differential Diagnosis," states that the book is an attempt to study medicine from the viewpoint of the presenting symptom. Of the thirty-three chapters devoted to symptoms, twelve are on pain alone. A study of pain and its symptomatic significance should, therefore, prove not wholly unprofitable.

Probably medicine presents no more fascinating chapter than the history of the efforts put forth to mitigate the sufferings of the human race. Simpson and Morton and others who have lulled with sweet nepenthe the physical sufferings of man, are deserving of a place on the bead rôle of fame along with the discoverer of methods of antisepsis. "Divinum est opus sedare dolorem," once spoke the father of medicine. The story is a long one. The first curative effort on the part of primitive medicine was bent toward the relief of pain. The "sorrow easing" drug was employed in the Homeric age. Indian hemp and the juice of the poppy were known to the ancient Egyptians. Every age and clime has contributed its quota to the relief of human suffering.

There is less known about pain than about any other symptom, largely because we know less about the nervous system than any other system of the body. Of metabolism of the nervous system we

*Read before the Medical section of the Wayne County Medical Society, Detroit, May 10, 1915.

know nothing, and of the functions of some parts of the brain our knowledge is almost as scant.

For the evolution of the race, as well as for the preservation of the individual, the pain sense is all-important. Max Nordau declares that without pain our lives would not endure an hour, for we would be unable to recognize danger symptoms and to guard against them. This thought is voiced also by Schleich, "Pain is a warner, an exhorter calling for defence, for fight, for the employment of all the measures of resistance and self-preservation." Crutcher maintains that pain is not to be reckoned as abnormal but as Nature's protest against the abnormal. Insensibility to pain, on the other hand, is often a grave symptom.

Metchnikoff speaks of the erratic nature of pain in both human beings and animals. Insignificant causes, certain forms of neuralgia, give rise to unbearable agony. The violent pain of childbirth is absolutely useless as a danger signal; on the other hand, such dangerous conditions as cancer and nephritis may exist for a long time without any discomfort to the individual. Weir Mitchell expressed himself on the mystery of pain as follows:

"What will implacable, beyond our kin,
Set this stern fiat for the tribes of men!
This none shall 'scape who share our human fates:
One stern democracy of anguish waits
By poor men's cots—within the rich man's gates.
What purpose hath it? Nay, thy quest is vain:
Earth hath no answer: if the baffled brain
Cries, 'tis to warn, to punish—Ah! refrain
When writhes the child beneath the surgeon's hand,
What soul shall hope that pain to understand?
Lo! Science falters o'er the hopeless task,
And love and faith in vain an answer ask,
When thrilling nerves demand what good is wrought,
Where torture clogs the very soul of thought."

A comprehensive idea of pain must be sought from a study of those organisms in which sensation merges from the simple state in which all stimuli have their corresponding movements, of which it is impossible for the organisms to have any conception. In these studies of the simpler forms of animal life no one is more deserving of an audience than Loeb. In the lowest forms of life, the nervous system is not a necessity but only an auxiliary in the life economy of the animal. In the earthworm each segment has its own special nerve supply. W. W. Norman has experimented with the simple earthworm and with vertebrates as highly organized as the fish, cutting off segments and mutilating the body without producing any movements. The reactions to injurious stimulation on the part of the lower vertebrates have led some to conclude that these forms of animal life have the same pain sensation as man. It has been found, however, that sharks may be operated upon without the slightest movement on their part. Norman's experiments go to prove that true pain phenomena do not make their appearance until we ascend rather high in the scale of vertebrates. Motor response to an irritant is not always an indication of pain; it may be nothing more than simple reaction to stimuli.

Loeb states that in his experiments on the tropisms of animals, it became clear to him how easy it was for an observer to regard machine-like effects of external stimuli on lower animals as the expression of intelligence. In regard to pain sensations of animals, Loeb believes that animals devoid of associative memory are also deficient in pain sense. Associative memory he defines as peculiar qualities of the central nervous system, whereby processes that occur there leave an impression or trace whereby they may be produced even under different circumstances than those under which they had originated.

According to Loeb: "Associative memory probably exists in most mammals. The dog which comes when its name is called, which runs away from the whip, which welcomes its master joyfully, has associative memory. In birds it is likewise present. The parrot learns to talk; the dove finds its way home. In lower vertebrates, memory is also occasionally found. Tree frogs, for example, can be trained, upon hearing a sound, to go to a certain place for food. In other frogs, Rana esculenta, for instance, no reaction is as yet known which proves the existence of associative memory. Some fishes evidently possess memory; in sharks, however, its existence is doubtful. With regard to the invertebrates, the question is difficult to determine. The statements of enthusiasts who discover consciousness and resemblance to man on every side should not be too readily accepted."

The same investigator expresses his conviction as to the ease with which an observer, inclined to look at things from the human viewpoint, regards the machine-like effects of external stimuli on lower animals as the expression of intelligence. Bethe also regards associative memory as a criterion for the existence of consciousness.

The reaction of an injured earthworm when it writhes and wriggles is naturally regarded as the expression of pain sensation, and some go so far as to regard these contortions as the expression of severe pain. This conclusion is not justified by the experiments of Norman, who found that if an earthworm be divided transversely, only the posterior piece makes the writhing motions, while the anterior portion crawls off, apparently unaffected. The anterior portion, which contains the brain, evidently experiences no pain sensations.[2] There is a tendency, almost universal, for man to interpret pain in the lower animals, and even in the lowest animals, in terms of his own sensation.

It is a physiological fact that the superficial parts of the body are well supplied with sensory nerves, while the deeper, internal portions are less richly provided. The brain, the center of the nervous system, is itself without sensation. Cushing was the first to demonstrate that the dura mater is insensitive to ordinary pain stimuli. The reason for these physiological phenomena is apparent when we consider that the brain and dura are well protected by the skull, and that the viscera are protected by the external portions of the body; that the skin, the "flesh garment" of the body is most richly provided of all with nerves of sensation.

The pain-sense, like the special senses, is largely a matter of mental and racial development. The self-mutilations of primitive peoples are not so much a matter of bravery as of the presence of a rudimentary pain sense. The horse with a broken leg will proceed to graze in the pasture with little apparent discomfort. Veterinary surgeons perform operations upon animals with little thought of administering anesthetics. Even in civilized man the pain sense requires to be developed; it is not born with him. The operation of circumcision is frequently done on newly-born male infants, who exhibit little evidence of pain. The "facies pathetica"

of the dog, horse, and some other animals, and the tendency to interpret pain in terms of our own sensation are responsible for those self-constituted sponsors of the lower animals—the antivivisectionists whose excessive zeal for the dumb animal makes them quite forget the welfare of the human offspring.

When a hard object is applied to the skin with greater pressure than is necessary to evoke the sense of touch, the sensation becomes one of pain and its severity is in proportion to the degree of pressure exerted. The sense of pain has been described as over-maximal stimulation of any form of sensory nerve (Starling). According to Howell, "For continuous pain at least, the evidence is very strongly in favor of the view that there exists a special set of fibers which have a specific energy for pain. It would appear that the pain sense has a punctiform distribution in the skin." When a pin or needle is pressed against the skin, the pain increases until just before the moment of penetration. An intestine may be cut or sewed without causing any sensation, while strong contraction of the intestinal muscles will evoke intense griping pain. Deep injection of fluids into the voluntary muscles occasions but little discomfort, while cramping of such muscles gives rise to disagreeable sensations of great severity. The feeling of muscle fatigue is on the bordeland of painful sensation. The quality of pain will be found to depend upon the kind of sense organ which is stimulated; for instance, pain described as "burning," means the stimulation of the pain sense as well as stimulation of the nerve endings of the so-called "warm spots"; a "throbbing" pain is due to local congestion with lymph, the throbbing being due to arterial pulsation, causing painful stimulation, the cadence of which is timed with the pulse. Many inflammatory pains are of this nature, and particularly if the site of inflammation be in the digital extremities. In addition to temperature and tactile spots on the surface of the body, there are spots from which pain may be elicited. In some parts of the body tactile and temperature sense is entirely absent, while pain is easily evoked. The cornea is a good example of this, as those who know, who have ever experienced the sensation of a foreign body in the eye. Under some conditions, chiefly pathological, pain sense may be wanting while tactile sense is normal.

We see, smell, taste, and hear by means of the mind, the sensation being referred to the respective organs of special sense. Likewise, pain is a matter of cerebration. Pain is much more severe if the attention be directed to it. An accidental, unexpected cut or bullet wound causes comparatively little pain at the time it is received, while the anticipated prick of the finger, necessary to obtain blood for examination, may cause a patient real agony. It is evident that pain is increased by the imagination. Undoubtedly this characteristic accounts for the greater severity of pain at night than during the day. Kant, the philosopher, a sufferer from gout is said to have mitigated his troubles by exercising more than ordinary self-control. Kant said: "Out of patience at feeling myself deprived of sleep, I soon seized upon the stoical expedient of fixing my thought intently upon some chance object, whatever it might be, and of consequently diverting my attention from all sensations. In this way the sensations speedily became blunted, so that the natural tendency to sleep overcame them. And this I could repeat with equally good results each time in the little interruption in my night's rest occasioned by recurring attacks. But in the morning the shiny redness of the toes of my left foot was sufficiently convincing to me that these sensations had not been purely fanciful." Undoubtedly some Christian scientists, under the spell of religious zeal, are able to efface their sensations. The ancient stoic held that pain, though evil, could be triumphed over by a mind properly disciplined.

Sensitiveness to pain varies with individuals; a strong willed person may suffer intensely without wincing, while the prick of a pin will greatly affect another. Some react to pain stimulus much more readily than others. As a general thing, those of thin build and neurotic temperament suffer more than the more robust. Carlyle once said, "With stupidity and a sound digestion man may confront much," but Carlyle himself belonged to the neurotic type and doubtless envied the so-called phlegmatic with the sound digestion. Cabot states that those patients who describe all their troubles as "terrible," "awful," "fearful," and the like, are apt to have lively knee-jerks, and that those more moderate in their expressions have usually less active reflexes, which would point to a parallelism between reflex sensibility and sensitiveness to pain. To establish the fact of pain it is necessary to take into account the facial expression and bodily movements. Emaciation or muscular weakness is apt to result from long-continued suffering. The account of an onlooker who unobserved watches the patient is also of value. Cabot maintains that severe pain almost always causes a notable rise in blood pressure, and if we find nothing of the kind we may rightly conclude that if pain is present it is probably not intense. The relation between the intensity of pain and blood pressure elevation is also corroborated by Curshman, who, in his experiments found that in 90 per cent. of people examined with normal sensibility the blood pressure arose from eight to ten mm. of mercury under stimulation with a faradic current on the upper portion of the thigh; in the remaining 10 per cent. it rose to fifteen mm. During gastric and intestinal crises of tabes and lead colic a pressure of 170 to 210 is common, quickly subsiding to 120 when the attack is over. During labor pains the blood pressure becomes higher, varying directly with the pain.

The diagnostic import of pain is the chief concern of the physician. Yet, dissociated from other clinical phenomena, it is apt to mislead. Alone it is a danger signal, as Richardson has said, "Alone, pain indicates danger in general; in combination with other signs it indicates danger in particular and guides the physician's hand to its source. The truth of this will commend itself to every one. Only recently the writer saw the case of a boy eleven years old with tenderness even on a slight pressure over the region of the gall-bladder, with little or no spontaneous pain or pain that could be elicited on pressure over McBurney's point. No jaundice, the only other symptoms were vomiting and elevation of temperature. A diagnosis of appendicitis was made and confirmed at operation. Every physician can relate cases where a diagnosis based upon pain alone would have been faulty.

Ross, in 1858, in his investigations on Visceral Diseases, thought that the impulses produced by irritation of the peripheral terminations of the splanchnic nerves were conducted by the posterior roots to the posterior horns of the spinal cord, where they diffused to the corresponding somatic

nerves and thus cause an associated pain in the territory of distribution of these nerves. He claimed that there were two forms of pain, somatic and splanchnic. Following the work of Hilton, Ross, McKenzie and Head, and more recent observers, the following facts may be crystallized. (Summary by Finney.) (1) That any nerve ending may be sensitive to some form of stimulation, which has been called the adequate stimulus, but insensitive to all others. The adequate stimuli for pain vary for different regions and structures of the body—for instance, those for visceral pain, are not of the ordinary tactile or thermal types, to which the skin and mucous surfaces so promptly respond, but are tension in some form or other. (2) That the threshold of pain, that is, the point at which pain as a result of any form of stimulation begins to be felt, may be raised or lowered, according to certain established conditions. (3) That tension in some form or other is the commonest, perhaps the sole cause of visceral pain.

Finney, of Johns Hopkins, is inclined to the belief of Ross that there are two forms of pain, splanchnic and somatic. It is almost impossible for the patient to localize a visceral pain. Ask him to point out the location of his discomfort and the average person will indicate in a vague indefinite way with all the fingers of his hand; ask him to use his index finger and he has some difficulty in accurately locating the pain. This is practically true of all visceral pains, whereas pains of the skin are located more or less accurately at the point stimulated.

According to Harris, "the theory of so-called referred pain is that somewhere in the common path the excitement of the splanchnic afferents is transmitted to the somatic afferents, and that the cerebral center for these being stimulated, the mind suffers an illusion and refers the source of irritation out to an area of the skin." The principal cause of referred pain is a lesion somewhere on the nerve circuit. When a lesion is located on a nerve trunk it is always referred to a point on the periphery distal to the area at which it occurs. Among the characteristics of referred pains are the following: They are not increased upon pressure or movement; they do not produce muscular stiffness as do inflammatory pains, and lastly, morphine as a rule does not relieve them for any length of time.

With the development of medicine diseases hitherto regarded as functional are gradually giving away to those having an anatomical basis. Thanks to the advancement of modern surgery, the foundation for a living pathology has been laid and we have anatomical causes for symptom complexes hitherto regarded as purely functional in origin. Abdominal surgery in particular has added to our knowledge of pain of that particular region. Again, the absence of pain, as in the case of certain breast tumors, points to the presence of malignancy; or the sudden cessation of pain in an appendix case, particularly if accompanied by corresponding fall in temperature, pulse rate, and leucocyte count, may be part of a danger syndrome.

According to Cannon,[3] pain has the effect of inhibiting the peristaltic waves of the stomach and the peristalsis and kneading movements of the small intestine. It has been shown also that excitation of the sensory fibres in the sciatic nerve for two or three minutes resulted in the inhibition of the secretion of gastric juice, which lasted several hours. Mantegazza (quoted by Cannon) has found that in human beings, pain interferes with digestion by lessening appetite and by producing various forms of dyspepsia with the arrest of gastric digestion, with vomiting and diarrhea. Violent pain may be accompanied by nausea and vomiting. Pain by reflex stimulation of the adrenal glands causes them to pour into the blood stream an increased amount of adrenin. "That the adrenal glands are subject to splanchnic influence has been demonstrated anatomically and by the physiological effects of their secretion after artificial stimulation of the splanchnic nerves. Impulses are normally sent along these nerves, in the natural conditions of life, when animals become greatly excited, as in fear, rage, and pain. There is a probability, therefore, that these glands are stimulated to extra secretion at such times. . . . Clear evidence has been secured that in pain and deep emotion the glands do, in fact, pour out an excess of adrenin into the circulating blood." (Cannon.) As a result follow; the liberation of sugar from the liver into the blood stream; alteration of the distribution of blood in the body, namely from the abdominal viscera to the heart, lungs, central nervous system and limbs; the shortening of the coagulation time of the blood. Regarding the increase of sugar in the blood, due to emotion or excitement, the relation between "flight instinct" and "fear emotion" and "pugnacity instinct" has been suggested. Since in wild life, fear and anger are likely to be followed by activities involving severe muscular exertion, probably the pouring out of sugar into the blood is Nature's way of coming to the aid of the laboring muscles. Darwin has drawn our attention to the fact that a "man or animal driven through terror to desperation, is endowed with wonderful strength, and is notoriously dangerous in the highest degree." . . . "In the agony of pain," he says further, "almost every muscle of the body is brought into strong action."

Crile has explained that with every injury there is a discharge of nervous energy. According to his kinetic theory of shock, the essential lesions of shock are in the brain cells. It is difficult to imagine the surgical shock of preanesthetic days. Inhalation anesthesia goes a long way toward mitigating the effect of surgical trauma upon the nervous system, by abolishing pain, which can be of no possible advantage to either patient or physician. Pain of surgical operation decreases the patient's resistance, exhausts his nervous energy, and delays convalescence. Crile has found experimentally that trauma, fear, and fatigue have similar effects on the brain cells. It is his belief that inhalation anesthesia does not go far enough; he speaks of it as only a "veneer." He reduces surgical shock to the minimum by eliminating fear and by the employment of local anesthesia to block the nerve trunks. Crile's work is a distinct contribution to medicine in its efforts to overcome the effect of pain and surgical shock.

Once pain has served its purpose as a diagnostic aid, it should be abolished for reasons which are self evident.

COMPLEMENT FIXATION IN CHICKEN SARCOMA.*

By CHARLES H. BAILEY, M.D.,

NEW YORK.

THE discovery by Rous of a tumor in fowls which can be propagated by a filtrate made from crushed cells or by the powder of dried cells, showed that in these animals, at least, there exists a new growth of a type entirely different from any as yet described, since no other tumors in animals, so far as is known, can be propagated by the means just mentioned. The natural assumption would be that this tumor is produced by a virus which is filterable, since it has been impossible, either by culture, by examining the fluid by ultramicroscopic methods, or by the study of stained sections, to demonstrate any parasite.

On the theory that if the growth were of parasitic origin the blood of the animal would contain a complement-fixing substance, the following experiments were carried out in the laboratory of the Crocker Special Research Fund at the suggestion of Dr. F. C. Wood. Sarcoma No. 1, which was kindly supplied by Dr. Rous, was employed in these experiments. Fixation tests were done on the sera of six Plymouth Rock and two white Leghorn hens, all of which had large tumors, the tests being controlled in each instance by sera from normal hens of the same species. The antigens used were made by extracting finely ground tumor tissue with (1) distilled water; (2) normal salt solution; (3) 95 per cent. alcohol, and (4) absolute alcohol. In some cases the tests were carried out with an antigen made of tumor tissue obtained from the hen which furnished the blood; in others they were performed with an antigen made from the tumors of the other hens. The general technique was the standard method now employed in carrying out the Wassermann reaction. In none of these experiments was a positive complement-fixation test obtained.

As a further control, blood from two pigeons which had been injected subcutaneously several times with the Rous chicken sarcoma, without takes, and from one normal pigeon, was inactivated by heating for twenty minutes at 55° C. Each of these three sera was then tested and found to be neither hemolytic nor anticomplementary. The antigen used was made from the breast tumor of a white Leghorn rooster, the blood of which showed no complement fixation when tested with antigen made from its own tumor. The tumor tissue was finely ground with sand; 2 c.c. of distilled water for each gram of tumor, and 0.5 per cent. of trikresol were added; and the mixture was shaken in a shaking machine for two hours, and then placed in the icebox for seven days. On removal from the icebox it was centrifugalized rapidly for ten minutes, and the upper portion of the supernatant fluid was used as antigen. On titration this was found not to be anticomplementary or hemolytic. When the test was set up in the usual manner a positive reaction was obtained with the sera for both inoculated pigeons, much more marked with one than with the other, while no reaction was obtained with the sera from the normal pigeon. Though this experiment may be regarded as controlling the methods used, it has no further significance, because to a pigeon the fowl tumor is a foreign protein, and, therefore, naturally induces the formation of an antibody. The important point is that in any animal in which the tumor will grow the protein of the neoplasm does not act as antigen and cause the formation of complement-fixing substances. This is true of the tumors of both animals and human beings.

Conclusions.—No complement fixation could be obtained in the blood of chickens bearing the Rous chicken sarcoma No. 1.

Complement fixation was obtained in the blood of pigeons which had been inoculated with the same tumor, the correctness of the technique employed being thus demonstrated.

These observations suggest that this particular chicken sarcoma may be a true tumor, though the proof is not absolute, for complement fixation has not yet been obtained in all of the known diseases in which a filterable virus is present. It is still possible, therefore, that there is a virus inducing tumors in chickens which does not give rise to complement fixation, but this would be exceptional rather than according to rule.

Since these experiments were completed, a paper reporting similar results has been published by Bürger (*Ztschr, f. Krebsforsch.*, 1914, xiv, 526), and for this reason we have omitted detailed protocols of our experiments.

*Presented before the New York Pathological Society, March 10, 1915.

Medicolegal Notes.

Liability of the Anesthetist.—One of two physicians separately employed, who undertakes to administer the anesthetic while the other performs an operation, is held in Morey v. Thybo (C. C. A., 7th C.) 42 L.R.A. (N.S.) 785, not to be liable for the other's negligence and malpractice in doing the work, if he has no actual knowledge of it.

Penalty for Illegal Practice.—The statute providing that any person who shall practise medicine in Kansas without having received and recorded a certificate from the State board of registration and examination shall be deemed guilty of a misdemeanor, and upon conviction thereof shall pay a fine of not less than $50 nor more than $200 (Gen. Stats. 1909, Sec. 8091), is held in State v. Cotner (Kan.) 42 L.R.A. (N.S.) 768, not to create a continuing offense involving a general course of customary conduct, but to penalize each specific act of practice defined in the preceding section (Gen. Stat. 1909, Sec. 9090).

Qualification of Experts—Testamentary Capacity.—In an action to contest a will a physician who had attended members of the testator's family, but had never rendered professional service to the testator himself, testified that he had seen the testator on occasions when he had been called to treat his mother, and had observed that his facial expression was very peculiar, such as is often noted in cases of epilepsy; that the testator was very reserved in manner, and would never engage in conversation. It was held that the action of the trial court in refusing to allow the witness to state his deduction from these facts as to the mental capacity of the testator was not an abuse of discretion.—Eckman vs. Funderburg, Indiana Supreme Court, 108 N. E. 577.

X-Ray Photographs as Evidence.—In order to show the nature of the injury sustained by a plaintiff suing for damages caused by a fall in the street an *x*-ray photograph was used, purporting to show a fractured rib and an injury to the shoulder. To elucidate his criticism of this picture another witness offered an *x*-ray photograph of a five-year-old child's breast to show the location of the ribs. It was urged that this was incompetent and prejudicial. But it was held that its significance was for the jury, who were advised that it was the picture of a child and not of a man of the plaintiff's age, and it might properly be used by way of illustration, like an ordinary map, diagram, or model.—Boddington vs. Kansas City, Kansas Supreme Court, 148 Pac. 252.

STAMMERING AND ITS RELATION TO AN ENLARGED THYMUS.

IN 1910 William Browning of Brooklyn advanced the hypothesis that stammering is associated at the start with the presence of an enlarged thymus, if not directly caused thereby. The subsequent study of twenty-five consecutive cases of stammering has tended to confirm this hypothesis. The histories of these cases cases and a complete analysis of the entire subject have been presented by Browning in an interesting and practical paper.*

The very multiplicity of the theories that have been proposed to explain the origin of stammering indicates how little is actually known about this condition. These theories regard stammering as an inherited weakness of the mechanism of speech, a developmental neurosis, an infective neurosis, an anxiety neurosis or fright inhibition, a disturbance of the cerebral or cortical speech centers, a transitory auditory amnesia, a spastic incoordination-neurosis, an ataxia of the speech mechanism, an associative aphasia, a mental tic, a disturbance of the will, a psychosis, a diseased state of the mind, etc. Browning cites numerous facts to show that stammering is not primarily a brain trouble. The subjects have shown as a rule abnormally acting speech mechanism. The condition develops at a certain period of life and practically never after youth. Stammerers may still be able to enunciate correctly in a singing or often in a whispering voice. Stammering is frequently recovered from and is rarely seen in brain affections. It is far more frequent in males than in females, which would tend to exclude the rôle of timidity or of hysteria. There is no confusion of thought for "the wit of stammerers is proverbial." There is no evidence of brain disease.

Previous work has shown that conditions in and about the upper air-tracts are of great importance in the causation of stammering. Among the conditions associated with stammering there have been noted adenoids, hypertrophied tonsils, nasal intumescence, enuresis nocturna, general hypotonia, with bad bodily carriage, shallow upper chest, palpable glands, various forms of habit spasm, and cardiac defects. There is one condition, which, according to Browning, is constantly present in all stammerers, namely, an enlarged thymus or evidence of a block in the thymic area. This is a generalization that might be regarded as one of sweeping nature if it were not made by a careful observer. The facts upon which this generalization is based are fairly well established. Twenty-five consecutive cases that all show the same anatomical abnormality and associated conditions that may be correlated with it ought to satisfy the most exacting critic. Browning's patients ranged in age between two and sixty-five years. In all of them there was unmistakable evidence of thymic enlargement. This was revealed by careful percussion. The charts accompanying the case reports show that this dullness corresponds to the upper half of the sternum and extends beyond its lateral borders, but more to the left than to the right. The dullness is relative rather than absolute, shades off gradually into the pulmonary resonance, and is usually continuous with the upper border of the heart. In some cases, usually in infants, or the very young, palpation may detect a portion of the thymus above the sternal notch. *X*-ray examination gives uncertain and inconclusive results. Prominence of the manubrium and an angulation at the junction of the manubrium and the body of the sternum have been noted by a number of observers. Dilated surface veins over the front of the chest are present in some cases of enlarged thymus, and are made prominent by exertion, excitement, or an ordinary cold. The relative immunity of females to stammering is attributed to the lesser frequency of thymolymphatism and the costal type of respiration.

The various conditions mentioned above which are associated with stammering are regarded as intimately related to the habit and as constituting with this a veritable "stammerer diathesis or complex." The lymphatic hyperplasia, including the enlarged tonsils and adenoids so frequently found in stammerers, goes hand in hand with the thymic hypertrophy. Muscular hypotonicity is one of the most constant concomitants of stammering. Recent experiments place the thymus among the glands of internal secretion which depress muscular action. A large percentage of stammerers show distinct bony anomalies, as rachitis, scoliosis, retrognathism, and a tendency to overgrowth, which fact seems to harmonize with the observation that lymphatism and the thymus are closely related to the processes of bony growth. Circulatory troubles and nasopharyngeal obstruction play an auxiliary rôle in stammering.

In what manner does the enlarged thymus tend to produce stammering? The answer is: by a reflex inhibition of the ordinary respiratory rhythm. A close analogy is furnished by the occurrence of asthma as a sequence of chronic nose and throat troubles, and more particularly of thymic asthma.

The therapeutic test furnishes the final argument in support of Browning's ingenious hypothesis. It has been well established that the *x*-rays cause a fibrosis of the thymus without completely destroying its glandular tissue. In the author's cases there was a progressive diminution in the area of thymic dullness under *x*-ray treatment and a con-

*Neurographs: A Series of Neurological Studies, Cases, and Notes. Edited by William Browning, Ph.B., M.D. Thymus-Stammer Number, Vol. I, No. 4. Brooklyn-New York: Albert T. Huntington, 1915.

comitant improvement in or disappearance of the stammering. The application of the *x*-rays demands special skill. Two to four treatments should be given at intervals of five to fifteen days, after which there should be a pause of several weeks. Two applications may suffice in the milder cases. Accessory hygienic, systemic, and local treatment may also be necessary in the individual case.

DIAGNOSTIC SIGNIFICANCE OF VOMITING IN GASTROENTERIC INFECTION.

THE most important factor in the treatment of a single symptom, such as vomiting, is the discovery of its proximate cause. This is not always an easy matter in the case of the vomiting associated with the acute gastroenteric infection of infants. In seeking this cause one may be guided by a few general principles, particularly by a consideration of the period of onset of the vomiting during the course of the disease.

In many instances the initial vomiting in a case of acute gastroenteritis or of enterocolitis is of reflex origin and may be classed with the vomiting that ushers in many other acute infectious diseases. The special indication for treatment in this condition is merely to provide rest for the stomach by withholding all food until the constitutional reaction accompanying the first few hours of onset of the disease has passed off. The initial reflex vomiting is usually not repeated. It may, however, be succeeded by the next type of vomiting, namely, that which is the result of the highly irritable condition of the gastric mucous membrane, which may be the seat of an intense congestion or of an inflammation, in either case of bacterial origin. The treatment of this type of vomiting in no way differs from that of any other type of acute gastritis as regards the withholding of food and water and the administration of gastric sedatives. But no type of vomiting yields so promptly to gastric lavage as does the persistent vomiting of acute gastroenteric infection of infants.

Vomiting that arises late in the course of the disease, or that recurs after a fair period of freedom from this symptom, must be interpreted differently from the initial or the early persistent vomiting of acute gastroenteritis. The actual causes of the late vomiting are usually unrecognized and the therapeutic measures resorted to in combating it are consequently futile. There are three main types of late vomiting, as follows: (1) Vomiting the result of meningeal or cerebral irritation from the desiccation produced by the loss of relatively large quantities of fluid by way of the gastrointestinal canal. The treatment is the administration of physiological salt solution by hypodermoclysis or by small rectal enemata. (2) Vomiting the result of an acetonemia accompanying the inanition from lack of food. This type of vomiting is relieved by the administration of alkalies by the bowel or by hypodermoclysis and often by the administration in the same manner of solutions of glucose. (3) Vomiting resulting from renal insufficiency. In this instance the treatment is identical with that of acute nephritis.

The above represent in their order of frequency the main types of late vomiting in acute gastroenteritis, but do not exclude the possibility of other types, which though extremely rare, must be borne in mind. Thus, one must consider the vomiting that ushers in a complicating or secondary infection, as pneumonia, meningitis, etc.; the vomiting of purely nervous origin that indicates on the part of the infant a disgust with the prolonged cereal feeding, and finally, the vomiting that may be characterized as agonal and that in a few instances immediately precedes the fatal termination.

THE RELATION OF THE PRACTISING PHYSICIAN TO PUBLIC HEALTH ADMINISTRATION.

THE practising physician has duties outside the sphere of his private practice, the chief of which is, perhaps, concerned with the work of local, State, and National Health Departments. His relation to work in this direction is discussed in Public Health Reports, June 11, 1915, by Dr. John W. Trask, Assistant Surgeon-General in the United States Public Health Service. It is pointed out that a principal function of the Federal health department is the control of epidemics and the prevention of the spread of disease from one State to another. This being so, it is important to consider the things essential to the work. It is impossible for any health department, be its statutory powers and available appropriations never so great, to control effectively any disease without first having information as to whether the disease is present in the community and, if present, how prevalent, and where and under what conditions cases are occurring.

There are two main classes of controllable diseases at present recognized. These are communicable diseases and occupational diseases. With but one or two exceptions every attempt at the control of communicable diseases other than by ascertaining the cases that occur, and the conditions under which they develop, has been a failure. Occupational diseases are due to industrial environment and can be prevented only by ascertaining what conditions exist which are capable of producing them in workmen. Each case of an occupational disease shows where conditions of this kind exist, for the fact that a case has developed is conclusive evidence of the presence of conditions capable of producing the disease. To ascertain where conditions exist which will produce these diseases, it is therefore necessary to know of each case that occurs, and the time, place, and conditions under which it occurs. For information regarding these the public health authorities are absolutely dependent upon the family physician. In the case of diseases due to improper living or housing conditions, an economic, social, or educational readjustment is required.

Unless the practising physician, however, is willing to co-operate loyally with the health department, the latter is greatly handicapped and its labors in the interests of public health are nullified to a great extent. Indeed the practising physician is essentially a part of the health department. As Trask says in conclusion "With the help and cooperation

of the practising physician the health department can do much to prove the truth of Pasteur's statement that it is within the power of man to cause all infectious diseases to disappear. Without the cooperation of the practising physician the health department can do little."

ENZYMATIC ADAPTATIONS.

In 1912 Ugo Lombroso published the results of a series of experiments in which he showed that no changes in the enzymatic content of the pancreatic juice can be detected after meals rich in fats, carbohydrates, or proteins. In other words, he could not confirm the observations made by Pavlov and his associates that after such meals the pancreatic ferments corresponding to the various nutrients undergo a notable increase in amount. Lombroso reports the results of his further investigations along this line in *Lo Sperimentale*, July 14, 1915. He finds that the normal defibrinated blood of the ox or dog has no hydrolyzing power when brought into contact with saccharose in vitro, but if either of the above animals has previously been treated with intravenous injections of saccharose, a slight inverting action in their blood serum can be demonstrated. The pancreatic secretion has no hydrolyzing action on saccharose, but acquires it to a slight degree after subcutaneous or intravenous injections of saccharose; and also after the ingestion of concentrated solutions of saccharose or of lactose, provided that this ingestion occurs on a fasting stomach. This circumstance considered in connection with the fact that small repeated doses of saccharose in the diet are not capable of evoking saccharose in the pancreatic juice, whereas they are capable of doing this if injected into the blood current, shows that the enzyme-evoking action of saccharose is not exerted upon the nerve terminals in the intestinal mucosa but through a direct action upon the blood. The production of saccharose can be evoked in the pancreas even after the latter is completely isolated from all nervous connections.

There is ample evidence, therefore, that the adaptive capacity of the pancreatic secretion is not dependent upon a nervous reflex but is the result of a direct chemical reaction in the blood in which possibly a hormone plays an important part. But defibrinated blood in vitro will not produce an inverting ferment when brought into contact with saccharose, which suggests the hypothesis that the living endothelial cells of the bloodvessels are an essential factor in this production, or that certain glands of internal secretion elaborate the ferment and pour it into the blood current.

A New Theory of Autoserotherapy.

The statement is often made that in certain cases of infectious disease antibodies are not produced, or not produced in sufficient quantities. In such way we explain the failure of the pneumonia crisis, the development of relapses, etc. Yet we have no proof that antibodies do not form in these cases. It is probable that they are always present and that for some unknown reason they are inert, or rather latent, and require activation by some unknown substance. Views similar to the preceding were expressed by Koenigsfeld at a meeting last winter of the Freiburg Medical Society (*Deutsche medezinische Wochenschrift*, June 17). It occurred to him that if serum containing such latent antibodies could be taken from the patient's blood and then reinjected it might become activated and would then prove an ideal serum. He tested the idea on some typhoid cases—26 in number. Into each patient he injected daily from 2.5 to 4 c.c. of the patient's own serum. The improvement, while transitory, was startling. The fever fell, the diazo reaction became negative, the mind became clear, diarrhea ceased, and appetite appeared. The average duration of the disease was from 18 to 22 days. In discussion Ziegler bore witness to the astonishing change caused by the injections, which appeared to prevent the development of complications. Berke had tested the principle in relatively benign cases of tetanus and noted the same specific influence. Of great value is the fact, if fact it is, that the patients carry a specific remedy with them.

What Evolution Lost Us.

In the *British Medical Journal* for June 26 Dr. W. A. Hollis, vice-president of the British Medical Association, lays aside his professional demeanor for the nonce and jests in polysyllables. In a discourse which he refers to as a "moral enthymeme," he takes some of the wind out of the sails of the arrogant disciples of Darwin by calling attention to a number of useful attributes which man has lost by evolution. First, to delve rather deeply into the human genealogy, there is the hydrozoan polyp which can be chopped in pieces and each segment will rehabilitate itself into a complete organism. Then there are the amphibia and crustacea which can renew limbs at pleasure, a quality which would certainly appeal to the recruiting officer in these parlous times, as would the property of molting enjoyed by some of them. Dr. Hollis laments the median eye once possessed by our ancestors and now marked only by the pineal gland. Such an organ favorably placed on top of the forehead would keep an automatic lookout for aerial invaders, while the other two eyes were attending to the routine business of everyday life. It is probable that certain of man's phylogenic forbears flew through the air, probably by means of membranes stretched over greatly prolonged hind ribs, and it is only very recently that man has been able to devise any sort of substitute for these. Now and then we see children born with supplementary ribs, mementoes of the volplaning lizard.

Typhus Mortalities.

As is well known, and as has been brought out in this country especially by the discussion in Brill's disease, typhus fever often runs a very mild course, but it always shows some mortality. At a meeting of the Royal Imperial Medical Society of Vienna in May last (*Berliner klinische Wochenschrift*, June 14) a number of practitioners reported low mortalities. Wenckebach's experience was confined to a peace epidemic in Holland in 1901-2. There were but 4 fatalities in 57 cases, 17 per cent. Granz reported that in what was at first a very deadly epidemic in a prison camp the mortality fell until it was only 2 per cent. Lindner saw a mortality of but 2 per cent. among Russian captives. The Ger-

man death rate was much higher. The most striking series is that of Skutetsky, who saw in 651 cases only 3 per cent. mortality. Teleky saw one death in 32 cases (3 per cent). There was a general consensus among the speakers at this meeting that an initial high death rate drops rapidly as soon as the measures for dealing with the disease are in full force. A higher death rate (19.5 per cent.) was reported by Tobeitz, and initial mortalities of 70 per cent. and 46 per cent. were recorded. The course of the disease is almost always mild in children, but the latter do not figure much in war epidemics.

Cell Proliferants in Wound Treatment.

Since the outbreak of the war there has been a notable silence in regard to the use of the new class of cell proliferant remedies in wound healing. There may be good reasons for this silence, such as prohibitive cost. According to some surgeons the new remedies possess no advantage over some of the old class—not even theoretical and experimental advantage. Balsam of Peru is one of our old resources which holds its own. It has even been claimed that petrolatum is distinctly a cell proliferant, and that the efficacy of Beck's paste in closing sinuses is due more to the petrolatum than to the bismuth. At Wilm's surgical clinic in Heidelberg and in the City Hospital in Schwenningen mineral oils are being used as cell proliferants (Military Supplement to *Muenchener medizinische Wochenschrift*, June 22). The subject is still in the experimental stage. It is claimed that the oil is a refined substance, so that none of its efficacy can be due to impurities. Thus far the source of the oil and the precise chemical nature have not been announced.

News of the Week.

A Warning.—Subscribers to William Wood & Company's publications are warned not to pay any money to the Cornell Educational Association of 416 North Clark street, Chicago, Ill., or to anyone representing this association, as it is not authorized to collect any money or solicit subscriptions for any of the publications of William Wood & Company. We recently published a warning not to pay any money to the National Educational Association, 130 Nassau street, New York City. The same names appear on the receipts issued by the Cornell Educational Association as are on those of the National Educational Association. Authorized collectors have proper credentials on the regular and well-known letter head of William Wood & Company. The authorization to collect appears over the signature of William Wood & Company.

Cholera in Central Europe.—The cholera situation is said to be quite grave in Austria, the minister of the interior of that country reporting that on August 19 there were 1,566 known cases of the disease in the empire. A despatch from Amsterdam, dated August 25, says that the rapid increase in the number of cholera cases in eastern Germany is becoming so alarming that a conference has been held at Thorn at which civil and military authorities discussed measures by which to cope with its spread.

The American Women's War Hospital Not to Close.—It is announced that the work of the American Women's War Hospital at Paignton, in Devonshire, England, will not be interrupted by the decision of the Red Cross to withdraw its nursing units from all belligerent countries because of lack of funds. An American surgeon has been appointed, who will have full charge of the hospital, with a nursing staff of American and English sisters.

Committee of American Physicians for the Aid of the Belgian Profession.—Dr. F. F. Simpson, Treasurer, 7048 Jenkins Arcade Building, Pittsburgh, reports the receipt, during the week ending August 28, of $10 from the Warren County, Miss., Medical Association. The total amount received has been $7,814.84; amount expended, $7,310.04, leaving a balance of $504.80.

New York City Death Rate.—During the week ending August 21, the total number of deaths was 1366 with a rate of 12.27, against 1381 deaths and a rate of 12.90 during the week ending August 22, 1914. There was an increase of six deaths from typhoid fever over those of the corresponding week of last year. The epidemic of measles is declining, the deaths from this disease having been fewer than during the corresponding week of 1914; this was the first week since March 27 that the weekly death toll of this disease was lower than that recorded last year. The death rate for the first 34 weeks of 1915 was 13.68 as compared with a death rate of 14.16 for the corresponding period of last year.

Dr. Willson's Lectures on the Heart.—Beginning with October 1 and continuing until April 28, Dr. Robert N. Willson will give his annual course of post-graduate lectures on the heart in the amphitheater of the Philadelphia General Hospital. The lectures are given every Friday afternoon from 5 to 6 o'clock and are free to all physicians and medical students.

Appointments to the St. Paul, Minn., City and County Hospital.—The following nominations for appointments to the attending staff of this hospital have been made by the medical department of the University of Minnesota: Dr. John T. Rogers, chief of the service in surgery; Drs. W. A. Dennis and A. R. Colvin, associates in general surgery, and Drs. H. B. Zimmerman and J. S. Abbott, assistants; Dr. P. B. Cook, associate in the branch of skin diseases; Drs. C. C. Chatterton and Wallace Cole, associates in orthopedic surgery; Dr. W. W. Lewis, associate in eye, ear, nose, and throat surgery; Dr. W. R. Ramsey, chief of the work in both pediatrics and contagious diseases; Dr. W. R. Beadie, associate in pediatrics; Drs. Bronson Crothers and C. E. Smith, Jr., associates in contagious diseases; Dr. T. L. Birnberg, assistant in contagious diseases; Dr. Ernest Hammes, chief of the mental and nervous disease section, with Dr. J. C. Michaels as assistant; Dr. J. L. Rothrock, chief in obstetrics and gynecology, and Dr. W. C. Rutherford, associate.

The Sanitation of the Mikvehs.—The Department of Health of New York City has for more than a year been interested in the sanitation of the Mikvehs. Through the medium of the Kehillah, the Vaad Horabbonim became interested in the problem and stimulated the formation of the Mikveh Owners Association. After a number of conferences extending over several months, plans for the sanitation of Mikvehs, satisfactory to the Department of Health, the Vaad Horabbonim and the Mikveh Owners' Association have now been completed and carried out.

Examination for Sanitary Bacteriologist.—The United States Civil Service Commission announces an open competitive examination for sanitary bacterologist, for both men and women, on September 22, 1915. From the register of eligibles resulting from this examination certification will be made to fill several vacancies in this position in the Public Health Service, for duty in the Hygienic Laboratory, Washington, D. C., or for field service, at a salary of $1,500 a year, and vacancies as they may occur in positions requiring similar qualifications. The duties of this position wll be to assist in the study of stream pollution, water supplies, and sewage disposal, and other public-health problems. Applicants should be competent to make the usual chemical and bacteriological examination of water and sewage. Graduation from a scientific course in a college or university of recognized standing or the degree of M.D. is a prerequisite for consideration for this position. Applicants must have reached their twentieth but not their thirty-fifth birthday on the date of the examination. This examination is open to all citizens of the United States who meet the requirements. Persons who desire this examination should at once apply for Form 1312, stating the title of the examination for which the form is desired, to the United States Civil Service Commission, Washington, D. C.

New York State Hospital Commission.—The Constitutional Convention sitting in Albany has voted to continue as a constitutional body the State Hospital Commission, which exercises supervision over the care of the insane. The convention rejected a substitute proposal which provided for a Secretary of Charities and Correction, with power of supervision over all State institutions, and a continuance of the Board of Charities, the Prison Superintendent, and the Hospital Commission as divisions of the Department of Charities and Correction.

Medical Appointments in Philadelphia.—The Civil Service Commission of Philadelphia announces the following examinations for positions in the Health Bureau of the Department of Health and Charities: September 16—Chief of the division of housing and sanitation, salary $3,100. September 17—Medical inspector (woman) in the division of child hygiens, salary $1,000. September 23—Assistant chief medical inspector, salary $2,400. September 24—Chief of the division of child hygiene, salary $3,000. The examinations are open only to citizens of the United States and residents of the city of Philadelphia.

Bequests to Charities.—The New Haven hospital is given a legacy in the will of the late Emma J. Knevels of New York. The estate amounts to $52,000. There are large bequests made in the will, and it cannot be determined as yet how much the legacy to the hospital will amount to.

The Second International Conference on Race Betterment was held in San Francisco August 4 to 8. The Conference discussed race decadence, the possibilities of race improvement, and the agencies of race betterment. Luther Burbank discussed "Evolution and Variation with the Fundamental Significance of Sex." Abundant, well balanced nourishment and thorough culture of plants or animals will, he said, always produce good results in holding any species or variety up to its best hereditary possibilities, beyond which it cannot carry them, and lacking which, maximum development can never be realized. But a sharp line must always be drawn between the transient results, temporarily attained through favorable environment and the permanent results of selection of the best individuals for continuing the race. Only by constant selection of the best can any race ever be improved. Paul B. Popenoe, discussing "The Natural Selection of Man," declared that there are only two ways to improve the germinal character of the race. One is to kill off the weaklings born in each generation. That is Nature's way, which we are all agreed must be supplanted. When we abandon that, we have but one conceivable alternative, and that is to adopt some means by which fewer weaklings will be born in each generation, to substitute a selective birth-rate for Nature's death-rate. That means eugenics. Dr. J. H. Kellogg proposed that the Conference institute a eugenics register which would undertake to register two classes of persons: (1) Those who, on examination in relation to personal characteristics and family pedigree, are found to measure up to eugenic standards: (2) the children born of parents whose pedigree and physical characteristics conform to the required standards. "Such a registry would be the beginning of a new and glorified human race which sometime, far down in the future, will have so mastered the forces of nature that disease and degeneracy will have been eliminated." Other speakers were Dr. David Starr Jordan of the Leland Stanford University, Dr. Ernest B. Hoag of the Los Angeles Juvenile Court, Edgar L. Hewett, Director of the United States Bureau of Ethnology, Irving Fisher of Yale University, and many others of prominence in sociological and scientific circles. The Conference was concluded with a Morality Masque, in which two hundred students of the University of California took part. This masque was a dramatic arraignment of disease and war.

Obituary Notes.—Dr. JOSEPH J. HIGGINS of New York, clinical professor of surgery in the Fordham University School of Medicine, New York, died at his home on August 22, aged 46 years. Dr. Higgins was graduated from the College of Physicians and Surgeons, New York, in 1892, was visiting surgeon to St. Vincent's and the Fordham Hospitals, and consulting surgeon to St. Mary's Hospital, Waterbury, Conn., and was a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Greater New York Medical Society, the Alumni Association of New York Hospital, the Hospital Graduates' Club, and the Bronx Medical Association.

Dr. MARC FONTAINE of Spencer, Mass., died at his home on August 9, after a long illness, aged 66 years.

Dr. JOHN AMBROSE KENNY died at Wilkes-Barre, Pa., on August 10, at the age of 40 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1909. Subsequently he served as interne in St. Agnes Hospital, Philadelphia, and later in Wills Eye Hospital.

Dr. CHARLES HERBERT BRADLEY of Minneapolis, Minn., a graduate of the Northwestern University Medical School, Chicago, in 1890, a member of the American Medical Association, the Minnesota State Medical Association, the Minnesota Pathological Society, and the Hennepin County Medical Society, and a former president of the last, and at one time instructor in medicine at the University of Minnesota, died at his home on August 1, aged 50 years.

Dr. Delano Stapleton Fitzgerald of Baltimore, Md., a graduate of the University of Paris, France, in 1880, died at his home on August 8, aged 62 years.

Dr. Azro P. Willits of Burlington, Iowa, died at his home on July 18, aged 65 years.

Dr. John Francis Conway of Brooklyn, N. Y., a graduate of the New York University Medical College in 1881, lied at his home on August 9, aged 60 years.

Dr. Elmer L. Styles of New Britain, Conn., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, Ohio, in 1881, died suddenly of heart disease while driving his automobile, on August 3, aged 68 years.

Dr. Charles Francis Preston Burchmore of Boston, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1893, died at his home in Winthrop after a long illness on July 26, aged 56 years.

Dr. Walter W. Wolfe of Fort Motte, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1879, died at a hospital in Columbia, following an operation, on July 25, aged 61 years.

Dr. Charles W. Higgins of Salt Lake City, Utah, a graduate of the Bellevue Hospital Medical College, New York, in 1867, died at his home on August 6, aged 74 years.

Dr. George W. Hackett of Ceres, N. Y., a graduate of the University of Buffalo, Medical Department, in 1895, and a member of the American Medical Association and the New York State and Allegany County Medical Societies, was instantly killed in an automobile accident on August 11, aged 48 years.

Dr. William H. Stowe of South Norwalk, Conn., a graduate of Yale University Medical School, New Haven, in 1888, president of the Norwalk Medical Association, and a member of the American Medical Association and the Connecticut State and Fairfield County Medical Societies, died suddenly from apoplexy on August 11, aged 73 years.

Dr. William S. C. Perkins of Norwich, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1860, and a member of the Connecticut State and New London County Medical Societies, died at his home, from diabetes, on August 7, aged 78 years.

Dr. Joseph Meyer of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1877, attending physician to St. Catherine's Hospital, and laryngologist and otologist to the Out-Patient Department, and a member of the Brooklyn Medical Society and the New York State and Kings County Medical Societies, died at the home of his son in Woodhaven, L. I., on August 15, aged 61 years.

Dr. Joseph Lawrence Hicks of Flushing, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1884, for many years attending physician to the Flushing Hospital, died at his home on August 19, aged 80 years.

Dr. Benjamin Edward Dolphin of New York, a graduate of the College of Physicians and Surgeons, New York, in 1904, assistant surgeon to the Out-Patient Department of St. Paul's Hospital, and a member of the American Medical Association, the New York State and County Medical Societies, the American Urological Association, the Association of the Alumni of the College of Physicians and Surgeons, the West Side Clinical Society, and the New York Academy of Medicine, died suddenly at his summer home in Far Rockaway, Long Island, on August 21, aged 37 years.

Dr. Charles Otto Maisch of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1891, assisting visiting physician to the Post-Graduate Hospital, Babies' Wards, visiting physician to the children's department of the German Hospital and Dispensary, and a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the German Medical Society, and the Society of the Alumni of the German Hospital, died suddenly, at the German Hospital, on August 20, aged 47 years.

Dr. Abraham Mayer of New York, a graduate of the College of Physicians and Surgeons, New York, in 1876, visiting physician to the Lebanon Hospital, consulting physician to the Jewish Maternity Hospital, and a member of the American Medical Association, the New York State and County Medical Societies, the New York Academy of Medicine, the Greater New York Medical Society, the New York Pathological Society, and the Metropolitan Medical Society of New York, died at his summer home in Allenhurst, N. J., on August 20, aged 60 years.

Dr. Thomas F. Aiken of Boston, Mass., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1894, died at his home on August 17, aged 45 years.

Dr. Florence Huson of Detroit, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1885, a member of the American Medical Association and the Michigan State and Wayne County Medical Societies, and for many years active in welfare work among women and girls, died at her home, after a long illness, on August 12.

Dr. Emily Myers Oberlin of Ann Arbor, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1909, and a member of the American Medical Association and the Michigan State and Washtenaw County Medical Societies, died recently at her home, aged 58 years.

Dr. Ammi Ward Follett of Somerville, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1881, former assistant superintendent of the Butler Hospital, Providence, R. I., and a member of the Massachusetts and Middlesex South District Medical Societies, died at his home, after a long illness, on August 15, aged 57 years.

Dr. Horatio N. Spencer of St. Louis, Mo., a graduate of the College of Physicians and Surgeons, New York, in 1868, founder of the *American Journal of Otology*, and editor from 1879 to 1883, professor of diseases of the ear in the Medical Department of Washington University, St. Louis, from 1881 to 1911, and a member of the American Medical Association, the Missouri State Medical Association, the St. Louis City Medical Society, and the American Otological Society, died in Atlantic City, N. J., after a long illness, on August 7, aged 73 years.

Dr. Louis Huber Schultz of Denver, Col., a graduate of the Medical College of Ohio, Cincinnati, in 1906, formerly connected with the National Jewish Hospital for Consumptives, and a member of the American Medical Association and the Colorado State and Denver City and County Medical Societies, was killed by the overturning of his automobile, on August 14, aged 31 years.

Correspondence.

DRS. KLEINER AND MELTZER MISQUOTED.

To the Editor of the Medical Record:

Sir:—At the April meeting of the National Academy of Sciences, Dr. I. S. Kleiner and the writer presented a communication, entitled, "Retention in the Circulation of Dextrose in Normal and Depancreatized Animals, and the Effect of an Intravenous Injection of an Emulsion of Pancreas Upon This Retention." This paper was published in the June issue of the Proceedings of the National Academy of Sciences, a publication which has only a small circulation. A few weeks ago we were surprised to find an article in the *New York American* stating that we had discovered the cause of diabetes and a cure for it. A day later a writer on foods published in an evening paper (in quotation marks) a statement, purporting to have been made by us: "Glucose in its natural form may be detrimental, but when manufactured is often fatal." That article contains many other nonsensical remarks. I enclose a reprint of our paper in question. You will see that we make no claim whatsoever to having found the cause of diabetes or a cure for it. Nevertheless a statement to that effect was spread all over the United States, and we are now receiving numerous letters from physicians and laymen, begging to send them the cure or to tell them what the cause of diabetes is. Similar letters are received by the Rockefeller Institute and by the National Academy of Sciences.

We beg you, therefore, to publish in your journal a statement that *our paper does not deal with the final cause of diabetes, nor does it even hint that we are on the way to find a cure for it.* We simply communicate there some scientific results which we have obtained in the course of a long series of experiments upon animals, without any reference to the practical applicability of these results.

S. J. Meltzer, M.D.

The Rockefeller Institute for Medical Research.

THE TESTING OF DISINFECTANTS.

To the Editor of the Medical Record:

Sir:—In view of the fact that the International Committee on the Standardization of Disinfectants, appointed at the last meeting of the International Congress on Applied Chemistry, cannot meet this year, owing to the war, and that this may entail a further delay of three years, we desire to call attention to one or two points which have arisen since the publication of our paper on "Approved Technique of The Rideal-Walker Test" (*American Journal of Public Health*, Vol. III, No. 6), and to submit the following suggestions as addenda to the paper referred to.

First, in view of the difficulty experienced by some workers not familiar with the technique of the chemical laboratory, we suggest that a burette, such as that described by Hermann W. Mahr, of the Board of Estimate and Apportionment, New York (*New York Medical Journal*, March 7, 1914), can be adopted in place of the dropping pipette. On the other hand we know many workers who have a decided preference for the dropping pipette originally used by ourselves and who do not see the necessity for changing this detail of the technique.

The second suggestion deals with the well-known variations in resistance offered by the standard broth culture of *B. typhosus*. To obtain the desired result in the phenol column—life in 2½ minutes and in 5 minutes, and no life thereafter—dilutions ranging anywhere between 1 in 80 and 1 in 140 may be required. We feel that this range is too great, and suggest, therefore, that the culture be rejected if it calls for a phenol dilution higher than 1 in 110, or lower than 1 in 90. Where the culture becomes so attenuated as to call for dilutions higher than 1 in 110, it can be strengthened by passage through any suitable animal. By restricting this range in dilution, the only rational objection to the Rideal-Walker test is at once removed.

A new difficulty has been introduced through the war; it is impossible now to obtain supplies of Witte's standard peptone. We understand this matter has been taken up by an American Committee, representing four prominent Laboratories, with Dr. Conn as umpire, and that this Committee is about to report in favor of a brand which is said to be equal to Witte's in every respect. In the meantime, it would be interesting to have the views of other workers. We, therefore, invite discussion on this point.

6. A Note on the Invasion of the Bodies of Infants by *B. dysenteriae*. C. TenBroeck.

2. **Institutional Treatment of Inebriety.**—I. H. Neff, recognizing that inebriety is a well defined condition, defines the inebriate state as follows: Inebriety is an expression of nervous weakness which is inherited—a psychoneurotic fault; founded on this weakness, manifestly a defect, is a habit one calls drunkenness. The inebriate is therefore the sum total of his personality or make-up. The author outlines the requisites of a State institution for inebriates as follows: A sufficient area of land to provide for agricultural development and for outside employment for the patients. A sufficient plant for industrial training. A tract of land of sufficient continuity so that there will be an opportunity for the segregation of the diverse cases. Adequate provision for both male and female inebriates. In the Massachusetts institution the acreage, over 1000 acres, is sufficiently large so that the above requisites have been met. The cottage or colony is the pivot center of the scheme. Three different colonies are considered. First, a hospital colony for men, which will take care of the hopeful cases; second, a detention farm colony which will provide for the more chronic and resistive type of patients; third, a hospital for women. Briefly expressed, the colony groups would care for the following types of patients: The cottages for men would receive: (1) Patients who come voluntarily or who are committed by the courts. (2) Young habitual drunkards placed on probation by the courts on condi-

tion that they spend a specified period at the hospital. (3) Suitable cases transferred on parole from the detention colony. (4) Non-criminal habitual drunkards committed by the criminal courts or received voluntarily as a condition of probation. The cottages for women would receive: (1) Patients who come voluntarily or who are committed upon application. (2) Cases placed on probation by the courts on condition that they spend a specified period at the hospital.

5. Bacteria in Stools in Infectious Diarrhea.—C. Ten Broeck and F. G. Norbury state that in order to isolate the dysentery bacillus from the stools of cases of infectious diarrhea, repeated attempts often have to be made, and the number obtained may be very few. Dysentery bacilli, of the mannite-fermenting type, were isolated from 68 per cent. of the seventy-nine cases studied. Organisms of the *Bact. welchii* type are occasionally associated with dysentery bacilli, but they are found more frequently in the cases of simple diarrhea and still more frequently in normal stools. The authors have no evidence that *Bact. welchii B. proteus vulgaris, Morgan's bacillus No. 1*, the paratyphoid bacilli, or *B. pyocyaneus* are the cause of infectious diarrhea, though these probably influence the course of the disease that is apparently started by the dysentery bacillus.

6. Systemic Invasion by Dysentery Bacillus.—C. Ten Broeck demonstrated *B. dysenteriæ* of the mannite fermenting group in the circulating blood of an infant suffering from infectious diarrhea. Eleven blood cultures made from other cases of diarrhea and cultures made from the organs of fourteen cases were all negative for dysentery bacilli, and the one positive finding is probably an accidental invasion rather than a usual feature of the disease.

1. Adolescent Insanity and National Health.—C. W. Burr, in discussing the prevention of adolescent insanity, states that one must stop the present tendency toward the easy life if one wished to develop a strong race and bring down the insanity rate. Moral and mental health are closely related, and the newest philosophy of life does not make for mental health. There is too much education and not enough training. There are too many people who read and there is too little that is worth reading. One hears too much of the rights of people, too little of their duties. Untold millions are spent in money and effort in trying to remove the stresses and strains of life, and relatively little in training youths to withstand stress and strain. Fortunately there are a good many cave men left, men who do not philosophize and are not learned and who of course are far from being sweetly good and superrefined, but who are firm fibred, with healthy natural instincts and mate with their kind, and train their offspring to have contempt for weakness, belief in self-dependence, respect for law, a desire for true righteousness, and love for strength and health. These cave men will by their descendants regenerate the race.

4. Sodium Bicarbonate in Hay Fever.—K. E. Kellogg has treated a series of fifty cases of hay fever during a period of three years. The first patient presented a general acidosis with a mild and transient glycosuria; the second a high specific gravity of urine with a marked acidity. Acting on the theory that the general condition served as a primary cause by reason of certain irritating qualities of the blood, making the mucous membranes hypersensitive, the author gave both patients sodium bicarbonate in dram doses three times a day. There followed such a marked relief from symptoms of rhinitis that the author felt justified in administering the same treatment to the remaining forty-eight. Reviewing the records, he finds that 90 per cent. of the patients enjoyed a marked amelioration of symptoms, and 70 per cent. complete relief after a few days' treatment; the remaining 10 per cent. were not as markedly benefited, although they all seemed to show some improvement. The improvement of the local symptoms seemed to be independent of the exciting cause. Some suffered from the inhalation of cotton weed; some, of rag weed; some, of wild rose; others of golden rod; and a few presented precedent lesions of the nasal interior. The alkali acted nearly the same in the majority of cases regardless of local or general conditions. It appeared to have a desensitizing action upon the mucous membranes. Possibly it may also have had some influence in keeping the toxins of the pollen from becoming soluble. In three cases the author found it necessary to supplement the treatment by the administration of a nasal spray of sodium bicarbonate solution.

7. The Appendicular Liver.—R. N. Duffy discusses this subject under two headings: (1) toxic hepatitis and (2) suppurative hepatitis. Soon after the onset of appendicitis, as early indeed as the second or third day, toxins elaborated in the appendix may make their way to the liver, mainly via the portal route, and there set up a toxic hepatitis. This condition was first described most clearly by Dieulafoy in 1898. A day or two after the onset of the abdominal pain in appendicitis, it may be noted that the patient is slightly jaundiced. The jaundice is rarely deep, and is usually limited to the conjunctivæ and the skin of the face. Its onset may make one doubt the original diagnosis and think of gallbladder and bile duct involvement. However, it is found that the tenderness is not over the gallbladder, but at McBurney's point. The liver is very rarely enlarged and palpation elicits practically no tenderness along its margin. The urine in these cases is of a dark reddish-brown color, suggesting the presence of bile. As a matter of fact, true bile is usually not present. When tested with fuming nitric acid the characteristic green and yellow rings of biliverdin and bilirubin cannot be seen as a rule, but a brownish disc is evident at the line of contact. Further tests prove this to be due to urobilin. The urine may further show a distinct trace of albumin and renal casts will be found in the sediment. These findings usually indicate a severe grade of appendicular inflammation; especially is this so if albumin and casts are present in the urine. The patient's symptoms may be all the while deceptively mild. Suppurative hepatitis, consecutive in the vast majority of cases to suppurative pyelophlebitis. The symptoms of toxic hepatitis develop early. The symptoms of suppurative hepatitis are later in their full development although the process is comparatively early in its inception. It is the product of microbic activity in the portal ramifications and the liver substance, whereas toxic hepatitis is due to the action of toxins alone. The picture is entirely different. Whereas toxic hepatitis is not associated with pain in the

region of the liver and the liver is not enlarged, as a rule; suppurative hepatitis, on the other hand, is associated with great pain in the hepatic area and marked enlargement of the liver. Suppurative hepatitis following appendicitis has its onset never earlier than the fifth or sixth day after the beginning of the appendix inflammation. It may follow an apparently mild attack. The patient may seemingly be convalescing well. There may be practically an entire subsidence of pain and elevation of temperature, a stage of "treacherous calm." The appendix may have been removed, say on the seventh or eighth day after the onset of the attack, but the mischief may have already started in the portal vein and then the appendectomy is futile. The chills occurring in this condition are most violent and the temperature rises high. The sweats are drenching. The liver enlarges rapidly and the enlargement may become enormous. The right lobe is usually more involved than the left. The spleen shows no enlargement. There are great hepatic and epigastric pain, much nausea, and vomiting, and diarrhea is quite a frequent complication. Jaundice may be early or late, slight or intense; the urine usually contains bile, albumin, and casts. The general symptoms are typhoidal, the tongue is dry and red. Practically all of the cases are fatal.

3. Subinfection from Foci in Pelvis and Abdomen.—H. G. Wetherill discusses the subject of chronic infections from local foci in the abdomen which he thinks have failed to receive the attention their importance merits. He criticizes Lane's theory of colon intoxication and his recommendation of the complete extirpation of the large intestine as hazardous and not supported by facts. The acceptance of this theory involves the admission of the permeability of the normal colon by a pathogenic organism, a theory which would appear to have been clearly disproved by Neisser. Their entrance into the circulation through damaged tissues, however, is a well-known fact, and they form foci which may become encapsulated by a fibrosis of adjacent tissues. During this process, however, the germs may be taken up by the blood and lymph channels and form foci in other portions of the body. Billings enumerates the common systematic results of such focal infection as chronic arthritis, one of the most common, nephritis, both acute and chronic, cardiovascular degeneration, chronic neuritis and myalgia. He cites among other local foci gastrointestinal ulcers, chronic appendicitis, cholecystitis and cholangeitis, and the genitourinary tract. Chronic catarrhal appendicitis may not only cause local disturbances, including digestive disorders, but may be the source of damage to the cardiovascular apparatus. It is probable that many of the pathological processes, called metastases are similar in their origin. Some recent experiments appear to prove that an abdominal disorder like appendicitis is often the result of a secondary hematogenous infection from the tonsil, and the author sees no reason why such a secondary focus in the appendix may not in turn be the starting point for extensive systemic disease. Lubarsch's recent studies show that germs can lie latent for long periods until trauma or inflammatory hyperemia enable them to produce a typical disease, and latent foci in the abdomen are not to be disregarded.

5. Intestinal Obstruction.—A. McGlannan states that the treatment of intestinal obstruction varies with the stage of the disease. Toxemia is the cause of death and is the important factor to be combated in the treatment. In the absence of toxemia the operative procedures are directed toward the removal of the obstructing cause and repair of any damage done the intestinal wall. When toxemia has developed measures must be devised for combating it, regardless of what may be done in direct attack on the obstruction. These measures are: First, enterostomy for the purpose of relieving the body of material which appears to be the source of the toxemia; second, supplying a large quantity of water, best by hypodermoclysis, in order that dehydration shall not take place, and to stimulate excretion; third, injection of suprarenal extract intravenously or with the subcutaneous water, to counteract the effect of the toxin on the heart and the blood pressure. Toxemia is the constant fatal factor in intestinal obstruction. This explains the slight effect of aseptic surgery on the mortality statistics of the disease. At present there is no certain detoxicating or antitoxic agent, and what slight improvement has been made in the results of treatment must be attributed to earlier intervention. Recognition of the disease in its early stage before the toxemia has developed and prompt operation in this early stage offer the only hope for reducing the high mortality rate of acute intestinal obstruction.

3. Hemoptysis Due to High Tension.—F. de Havilland Hall describes a group of cases which drive home the conclusion that in certain cases of hemoptysis the cause is to be sought in the condition of the vascular system rather than in pulmonary tuberculosis. It is most important from the patient's point of view that this condition should be recognized, as a different line of treatment is required in the hemoptysis due to high tension. The author advises inhalation of nitrite of amyl at the time of the hemorrhage, with low diet, and not too much liquid. When the bleeding has been arrested, then attempts should be made to regulate the patient's mode of life so as to reduce the high blood pressure. The prohibition of alcohol, the limitation of meat and salt, and a generally restricted diet are indicated. If the patient be engaged in business his hours of work should be abridged, and if the case be a serious one it may be necessary to advise that all work be discontinued for a time or even permanently. The skin should be kept active by means of warm baths, and a

daily action of the bowels, a rather loose bowel movement being aimed at, should be secured. Drugs such as the iodide of potassium and lithium hippurate should be given, and an occasional dose of calomel or blue pill is most useful in lowering tension. By these means further hemoptysis may be prevented and the patient's life prolonged, but should apoplectic symptoms threaten prompt venesection should be carried out.

2. Treatment of Gas Poisoning in Transvaal Mines.—A. H. Watt and L. G. Irvine state that every man who has been exposed to nitrous fumes must be kept under observation, in hospital if possible, for at least twenty-four hours. An emetic of copper sulphate, 8 grains, followed by a large quantity of water, is given, or a hypodermic injection of apomorphine. It is imperative that vomiting should be freely induced. If an emetic is given early, any other treatment except rest in bed for a day is not usually required. The onset of dyspnea and cyanosis is watched, and should moist sounds develop at the bases of the lungs bloodletting is employed, and as much as a pint may be withdrawn from a vein in the arm. This is usually difficult, as the blood is tarry and coagulates very rapidly. The authors have transfused with saline to replace some of the blood withdrawn. Atropine may be given hypodermically. Inhalation of oxygen is also useful. Should symptoms of general edema of the lungs develop, the prognosis is extremely grave. Very few recover when this stage has been reached. To illustrate the efficacy of treatment, the following case is quoted: In one of the mines under the care of one of the authors a case of gelatine was accidentally set on fire. The fumes spread through the workings, and fourteen men were "gassed." Thirteen of them immediately had an emetic, and the next day were all out of danger. One man disobeyed orders, and went home without receiving an emetic. He was sent for, but he had gone out for a stroll after having partaken of a hearty luncheon. He was found four hours after the accident, and came to hospital under protest, stating that he felt quite well. In the evening he developed general edema and congestion of his lungs, and died before morning.

4. Isolation of Typhoid and Paratyphoid Bacilli from Feces.—C. H. Browning and L. H. D. Thornton describe their method as follows: Specimens of feces should be cultured within several hours after evacuation. In cases in which feces are normally solid it is advisable to give purgatives and examine the resulting fluid motions. Make the usual smear cultures on plates of solid medium containing an indicator—for example, Endo's or MacConkey's. At the same time inoculate peptone water containing brilliant green; employ preferably a series of tubes for each specimen, but when time prevents this, use a concentration of 0.5 c.cm. of 1 in 10,000 brilliant green in 10 c.cm. of medium. The direct plates and the brilliant green peptone water cultures are then incubated; if typical colonies are not found on the direct plates, or if "likely" colonies are scanty, make subcultures (successive strokes) from the green tubes on Endo's or MacConkey's medium. These are then incubated for twenty-four hours and examined in the usual way; should typhoid or paratyphoid bacilli be present in the subcultures from brilliant green medium they usually occur as an abundant growth of typical colonies, and it is possible to proceed at once to identify them by the usual fermentation and serum reactions. In certain cases in which green resisting organisms are present positive results may be obtained only when telluric acid is employed, in addition to green, in the medium. The cultures in the green telluric acid mixture may be made simultaneously with the others, or this medium may be reserved until the other procedures have failed. Thus, should direct plates fail to yield positive results, and the green medium be overgrown (inosite fermenters), then, in further examinations of the case, employ, in addition, peptone water medium containing a mixture of brilliant green with telluric acid.

7. Inversion of Uterus in a Nullipara.—R. B. Johnston reports a case of this condition, the unusual feature being the inversion of the uterus in a nulliparous woman aged 45 years. The condition was produced by the efforts of the uterus to expel a polyp as a foreign body. Owing to its close attachment to the fundus, the tumor gradually produced a dimpling, this process extending until the uterus was completely inverted. It was reduced with great ease and quick and steady recovery from the severe shock resulted.

Berliner klinische Wochenschrift.

July 12, 1915.

Bedside Study of the Bile.—Bedark and Pribram sum up their study of this subject as follows: By means of the duodenal sound and quantitative estimation of the coloring matters and cholesterin of the bile it is possible to arrive at valuable conclusions. Finds in connection with increase in coloring matters refer to increased destruction of erythrocytes—so-called hemophthisis. A strong increase of biliary coloring matter is certain evidence of a hemophthisis, and with beginning anemia indicates splenectomy, a resource which is at once followed by a restitutio ad integrum. This association has never been shown in fistula experiments on animals. The absence of urobilin in duodenal secretion shows the absence of an enterogenous infection of the gall ducts, but the converse cannot be inferred, *i.e.* the presence of urobilin is not pathognomonic of enterogenous cholangitis; urobilinocholia may also mean insufficiency of the liver. There is a physiological breaking down of erythrocytes during menstruation, *i.e.* the ordinary destruction is increased. The cholesterin content of the blood is increased in cholelithiasis, hypertrophic cirrhosis, catarrhal jaundice, and also in diabetes and certain nephritides. In atrophic cirrhosis the amount of cholesterin is decreased. Whenever the blood content of cholesterin is increased there is diminished excretion in the bile. After splenectomy the blood cholesterin increases and the bile cholesterin decreases. In pregnancy the cholesterin of the bile sinks with each month until at term only imponderable traces are found.

Temperature Measurements by Medical Men.—Wintritz begs his readers to study carefully the statements in his article. He has practised medicine for twenty-seven years and believes that temperatures are not taken with sufficient pains nor interpreted with sufficient feeling of responsibility. He finds that most of his colleagues rely on axillary temperatures. It is now univer-

sally admitted that normal human temperature is never over 37° C. (98.6° F.). The old estimate of 37.5° C. as a "normal maximum" is too high. Anything about 37° is suspicious, and if accompanied by quickened pulse, headache, neuralgia, general prostration, thirst, anorexia, etc., fever is certainly present. If all these symptoms are absent fever is not excluded. There is no definite relationship between axillary and rectal temperatures, as a result of which we can add an increment to the former which shall then represent the norm. The said differences may be only a few tenths of a degree or as much as one to two degrees. It is true that there is an average difference of one-half to one degree, but this does not help in the individual case. The mouth temperature may be only one-tenth of a degree below normal, but only rectal and vaginal temperatures represent the actual body heat. We know that very slight local disturbances—coryza, gastric and intestinal irritation by ingesta, constipation, etc.—can affect the rectal temperature, doubtless by minimal absorption of material which can disturb the heart center, and that the patient may at the same time feel perfectly well. In other cases the patient feels poorly and complains much, yet there is apparently no temperature rise nor local foci of disease. These patients are an opprobrium, because they are usually treated by general roborants and often find their way to quacks. When a diagnosis is made it is apt to be anemia, nervous debility, or rheumatism. Proper thermometry, by showing temperature and pointing to a local focus of disease, would remove this reproach. In such cases, too, the temperature must be carefully followed up. These cases of mild toxemia often lead to acute infectious nephritis from absorption of bacteria. We are accustomed to watch for nephritis in scarlatina, along with other complications, and so in other severe illnesses. Even here, however, we often become lax during convalescence. Thermometry has great possibilities in the detection of simulation and in life-insurance examination. The author relates observations which illustrate his thesis.

Münchener medizinische Wochenschrift.

July 13, 1915.

How Can Soldiers with Weakened Vision Be Enabled to Read?—Stock refers to the provisions made for instruction of the totally blinded in new vocational work and then passes on to consider those who retain some vision but are no longer able to read. Most of the men in question have sustained transverse wounds of the skull with comminution of the bones of the orbit. The optic nerve may have been directly injured or involved in a hemorrhage or there may be various kinds and degrees of injury to the bulb—lacerations of the retina or choroid. Some weeks or months may be required before the exact degree of damage can be ascertained. If central vision is then good we need not concern ourselves with contraction of the field of vision. If there is only one eye with good central vision we need have no fear that it will be overtasked. If central vision is lost outright or reduced to one-third or one-quarter the patient becomes a subject for our efforts. Even if he is a peasant he must read the papers and such letters as he receives, although he will be as able as before to earn his living. If he has a calling which demands close work with his eyes he will be forced to change it if his vision cannot be improved. This can be done, even if vision is but one-tenth, by using ordinary magnifying lenses. But the far vision is equally defective, and telescopic lenses must be used to get corresponding results. Without prisms objects of distant vision can be magnified but twofold at most, but when prisms are employed sixfold may be reached. Many of the wounded men were shortsighted to begin with. Thus one soldier was not accepted for service until provided with certain lenses. Shot in battle he lost the sight of the right eye. The left eye gradually improved, but vision with ordinary lenses was but 5/50. As he was a theological student ability to read was paramount. By using special magnifying systems acuteness was raised to 5/10. Much practice was required before he could read fluently, and he complained of the narrowness of the visual field and lack of distant vision. In a man who had been emmetropic and had lost the sight of one eye, with the other badly crippled by lesions of both opticus and bulb, 5/50 of natural vision still remained. This was raised by magnifying systems to 5/12. As he is an innkeeper he can pursue his calling without hardship.

Yerba Maté as a Substitute for Tea and Coffee in the Field and in the Hospital.—Richter writes in praise of Paraguay tea, which he has drunk for over twenty years. Any substitute for coffee and tea must be readily made, cheap and not prone to deteriorate, must quench thirst and not stimulate, and have a pleasant taste. Large supplies of yerba maté are in the Bremen warehouses, and the price, slightly higher than before the war, is about 25 cents a pound. The tea comes both in dried leaves and powder, and an infusion is easily made, as in the case of ordinary tea. Hot or boiling water should be used and the infusion allowed to stand for ten minutes. The leaves, which are relatively heavy, fall to the bottom, and a strainer is not required. From 10 to 12 gms. makes a liter of tea. From the grounds further infusion may be made with fresh hot water. Paraguay tea may be drunk either hot or cold, plain, sweetened, or acidulated with lemon or wine. While the infusion contains some caffeine it never causes insomnia. It quenches thirst better than either tea or coffee, yet is devoid of the least bitter taste. Drunk lukewarm it exerts this thirst-quenching property to the full, hence it is not necessary either to heat or chill it. A slight smoky taste, if found disagreeable, may be removed by parching the herb in the oven.

Deutsche medizinische Wochenschrift.

July 8, 1915.

Indications for Intervention in Graves's Disease and Operative Results.—Starck has operated on sixty-nine patients with Graves's disease and has secured 30 per cent. of recoveries and from 30 to 45 per cent, of improvement. His operative mortality was 9 per cent., and some of those who were not improved by intervention became worse. In view of the prevalent opinion that a persistent thymus means a fatal outcome of operations, this organ must always be looked for, and if present it must either be resected or have its bloodvessels ligated. In operating for Graves's disease general narcosis must be the choice in the very nervous, myasthenic, psychopathic subject. The other patients get along with local anesthesia. Operation is really contraindicated when there is a status lymphaticus, but may be done with local anesthesia. In many cases a successful operation will pave the way for intensive medical treatment. In the *stadium incrementi* of the disease operation is contraindicated; intervention belongs to the stationary or latent periods. Best suited for operation are cases of Krauss's goitre heart and classical cases of Graves's disease. In the nervous-myasthenic type with little involvement of the heart operation accomplishes but little. The size of the thyroid on palpation does not constitute a factor in operative indications. Better results are expected with small, soft thyroid than large, firm organs. The blood picture likewise is not a factor in indications.

Gastroenteritis Paratyphosa.—Hake recalls that infection with the paratyphus B causes two clinical types

of disease, viz., a paratyphoid fever and a gastroenteritis; also that these infections have been associated with meat poisoning. He relates two cases which occurred in troops in which gastroenteritis paratyphosa was the diagnosis. As often happens the meat ingestion is a pure hypothesis. We know now that the paratyphus B occurs in nearly all our nutriment. The two soldiers, although in a garrison, upon a common regimen, were the only ones to be attacked. Prompt isolation, in the author's opinion, prevented an epidemic, as the disease can surely be spread by contact. In the first case the disease began sharply with chills, hoarse voice, diarrhea, and vomiting. The spleen showed no enlargement. The extremities were cyanotic. Cholera morbus was at first suspected (the paratyphus form), but the state of the pulse and temperature and the absence of rice-water stools spoke against this presumption. The Widal was negative in this patient. The case ended fatally and the diagnosis of paratyphus infection was not in doubt. This patient had subnormal temperature throughout. The second patient, who recovered, was taken ill rather insidiously, first having diarrhea and colic, for which he received opiates. As he did not mend the diagnosis was made of simple gastroenteritis, altered later to dysentery. He had fever, and a positive Widal, while the paratyphus B was found in the urine and stools. A negative Widal by no means excludes paratyphus infection (the author refers of course to clumping the paratyphus B). When true cholera is simulated the prognosis is grave, but subnormal temperature does not necessarily aggravate the prognosis. Sudden onset with diarrhea and vomiting suggests a choleriform infection as well as acute poisoning. Colitis seems to be always present in all paratyphus B infections. The clinical types vary much. In one case local symptoms predominate and we see acute gastroenteritis and cholera-like symptoms, pseudo-dysentery, etc. In another, ordinary typhoid is simulated by a combination of local and general symptoms. In a third type we see an extensive bacterio-toxemia—a sepsis with metastasis throughout the body.

July 15, 1915.

Dihydromorphin and Diacetyldihydromorphin.—Kolb has been testing these morphin derivatives as substitutes for morphin. He first sought to learn the dose of hydrated morphin, and made use of operated goiter patients for this purpose. In this way he found that with hydrated morphin twice the dose of ordinary morphin is required. In regards to quality of action this appeared to be the same in hypodermic exhibition but hydrated morphin cannot well be given by mouth for it has a marked tendency to cause vomiting. In fact it could well be used as an emetic, were it not for the fact that its action was both slow and distressing. It no doubt acts by causing pylorospasm in a much higher degree than does morphine. In the protracted use hypodermically of hydrated morphin there was no demand for an increased dosage; in other words it is not habit forming. As is well known diacetylmorphin is heroin, and the anthor also tested hydrated heroin. This is well tolerated both by the mouth and hypodermically under conditions: *i.e.* up to a certain dosage vomiting is rare—as rare as with morphin; above that dose, however, it begins to be common. Hydrated heroin, like hydrated morphin, is not a habit-forming drug. The two drugs have been used throughout to fill the indications for morphin.

Angina Pectoris and Raynaud's Disease.—Schott of Nauheim states that war has introduced new clinical pictures of diseases. This is true especially of diseases of the circulatory system, with or without a nervous component. Infections, febrile affections, attack men who have been undergoing incredible hardships. A soldier, aged 37, had a clean record in most respects. He had always drank considerable beer. A mason by trade, his hands and feet had never been cold during the winter. He bore the hardships of war well. His work was driving a munition wagon and the dust given off from the explosives was irritating to the air passages and at last became a hardship. He constantly coughed, sneezed and spat up mucus tinged by the yellow and green explosive material. His fingers now began to show the symptoms of beginning Raynaud's disease. The troop surgeon allowed him to stop at intervals to warm his hands, but nothing was of any benefit and when blebs developed on his fingers and he could no longer feel anything he was laid off permanently. Examined in the Reserve Hospital he was found to be well nourished, weighing 176. There was no fever. The lesions were limited to the fingers and hands and the toes. The *x*-ray showed that the bony skeleton was still intact. The nervous system was normal, aside from the sensory disturbances in the extremities. In about three weeks thoracic symptoms developed. The patient was found to have the lungs which characterize stone cutters and other workers in dust and this was explained by his trade of mason. The state of the heart and vessels was highly complicated and repeated examinations were made before a diagnosis could be reached. Both the radial and ankle pulse were at times imperceptible and there was a marked asymmetry. A full radial on one side would be associated with absent radial on the other. The cardiac finds also showed irregularity. The area of dullness, the heart sounds, etc., were inconstant. As the composition of the explosive was a secret no exact information could be obtained about a possible chronic intoxication. Picric acid could be excluded through the spectroscopic finds in the blood. It was finally assumed that nitrites were in part the offending agent and it was shown that nitrobenzoic acid formed from nitrotoluol was able to cause the syndrome from which the patient suffered. Some of the symptoms, such as precordial pain on climbing stairs could be summed up as stenocardia, due apparently to beginning arteriosclerosis. These yielded to nitroglycerin and diuretin. Arteriosclerotic angina was, however, associated with the vasomotor or functional type. The same combination of the functional and organic was also evident in the Raynaud's disease. The extreme instability of the heart, aorta and arteries, as to form and function, seemed to be a direct result of the chronic intoxication; but Schott, despite his experience in circulatory pathology had never before seen such manifestations.

Tonsillar Extract in the Treatment of Diabetes.—G. B. Farmachidis concludes on the basis of animal experiments and clinical observation that an extract of the faucial tonsil named by him "glycolytic amygdalin" has a definite therapeutic value in simple glycosuria and in diabetes mellitus. The extract is administered by mouth.—*Riforma Medica.*

Cardiac Stimulants and the Coronary Arteries.—Sakai and Saneyoski find that toxic doses of strophanthin produce a contraction of the coronary arteries, but that moderate or therapeutic doses have no such effect. Likewise therapeutic doses of caffeine and diuretin cause no coronary constriction; on the contrary they produce, although not constantly, a dilatation of the coronary arteries.—*Archiv für experimentelle Pathologie und Pharmakologie.*

Insurance Medicine.

Value of Blood Pressure Readings in Examinations for Life Insurance.—The value of systolic blood pressure readings in the selection of life insurance risks has been demonstrated, but Dr. J. W. Fisher, medical director Northwestern Mutual Life Insurance Company, Milwaukee, Wis., presents the reasons for this conclusion. To begin with there was comparatively little information to be had as to what constituted a normal systolic blood pressure. Therefore, when, in 1906, the Northwestern Mutual Life began to use the sphygmomanometer, their first effort was to establish average readings at the various ages. Clinicians had considered a systolic pressure of 170 or 180 mm. as of little significance, but the figures which were obtained by the study of 13,000 readings in 1911 showed that these figures were much too high.

Within the last year (1914) the correctness of the averages obtained has been verified by the medical department of the Mutual Benefit in a series of 4325 cases and by 2000 or more additional readings of the Northwestern Mutual Life. The statistics here given were compiled from the 19,339 readings mentioned above: Age 15-20, showed an average pressure of 119.85; age 26-30, an average of 123.65; age 41-45, an average of 128.56; age 51-55, an average of 132.13, and 56-60, of 134.78.

At the present time a blood pressure reading is required of all applicants, irrespective of age or amount of insurance applied for. Up to May, this year, 405 applicants, under age 40, who had a persistent systolic pressure of 15 mm. or more above the average for their respective ages, without any other impairment recorded on the blank, were rejected by the Northwestern Mutual Life. Between the ages 40 and 60 similar rejections numbered 1036.

The company accepted 2661 risks, ages 40 to 60, between 1907-1910, with an average systolic pressure of 142.43 mm., which show a mortality about the same as the general average mortality of the company for the same period. Of this number up to August 1, 1913, the actual deaths were 85, while the expected deaths, according to the actuaries table, should have been 172.326—a per cent of actual to expected of 49.33. According to the recent medico-actuarial table, the expected mortality of this same group is 113.966, giving a per cent of 74.58, using this group as a basis. The Northwestern's average mortality is only about 80 per cent of the medico-actuarial table.

During the same period, 1907-1910, 525 applicants of all ages were granted insurance whose average systolic pressure was 152.58 mm. This group, designated Group A, showed a mortality of over 30 per cent above the general average of the company. There were thirty-three deaths up to August 1, 1913. The expected deaths, according to the actuaries table, was 42.799, a per cent of actual to expected of 77.10.

Another, Group B, of 1970 lives, all ages, with an average systolic pressure of 161.44 mm., showed a mortality almost two and one-half times greater than the company's general average mortality. These cases were all rejected. Of these, as far as could be determined, 83 died. There may have been more, for all the rejected applicants could not be followed. The expected deaths, according to the actuaries table, were 67.200, the actual deaths 83, a per cent of 121.51.

Group B may be divided into two classes: C, 1082 with no impairment except the high systolic pressure—average 159.90. D, 888 with high systolic pressure and one or more impairments—average 164.77. These impairments included the following conditions: Arteriosclerosis, heart murmur, heart hypertrophy, albumin and sugar, or either alone, albumin and casts, nervous symptoms, etc. In Class C there were 40 deaths. The expected deaths, according to the actuarial table, were 34.778, a per cent of actual to expected of 115.02. Class D showed forty-three actual deaths. The expected deaths, according to the actuaries table, were 32.422, a per cent of actual to expected of 132.63.

Accordingly, the mortality was greater in the class where one or more impairments, besides the high systolic pressure, were found; but where the high pressure was the only impairment, the mortality was more than twice as great as the company's general average for the same period.—*Lancet-Clinic*, Feb. 18, 1915.

The Relations Between the Life Insurance Agent and the Local Examiner.—In a paper read before the Medical Life Insurance Section of the Texas State Medical Association, Dr. P. H. Scardino says the examiner enjoys a triple relationship with company, applicant, and agent. Consequently he is in a fair way to enjoy the wrath of all three. Primarily, the life insurance examiner is in the employ of the company. Therefore, the benefit of a doubtful risk is always given to the company.

Fairness, promptness, and courteousness to company and agent are watchwords for the examiner. The agent is entitled to all due respect, promptness, and courtesy for he is the producing end without whom a life insurance company would soon fall by the wayside.

Every applicant should receive a good thorough examination, repeated examinations if necessary, so that we may be doubly sure we are not rejecting a good risk.

The diplomatic physician always secures a reluctant applicant and sends him away contented. He will further protect the good natured rivalry between agents, and will not leave applications lying around on his desk, where rival agents will have every access to them.—*Texas Medical News.*

The Endowment Policy an Incentive to Live.—At a meeting of the Life Underwriters' Association of New York in the Hotel Astor last spring Arthur Hunter, actuary of the New York Life Insurance Company, read part of a report on mortality in the United States compiled recently by an investigating committee appointed by forty-three of the leading life insurance companies of America. It had been found, among other things, that the mortality rate among women who took out twenty-year endowment policies was lower than among women who took out ordinary life policies.

This fact, Mr. Hunter said, appeared to support the theory of the influence of mind over matter in producing longevity. "The woman who expects to receive the principal of her insurance if she lives twenty years," he said, "generally determines to live twenty years and get it, whereas the woman who has insured herself for the benefit of heirs has no incentive of the kind."

Book Reviews.

AN INDEX OF PROGNOSIS AND END-RESULTS OF TREATMENT. By Various Writers. Edited by A. RENDLE SHORT, M.D., B.S., B.Sc. (Lond.), F.R.C.S. (Eng.) Captain R.A.M.C., Hunterian Professor, Royal College of Surgeons; Examiner in Physiology for the F.R.C.S. Hon. Assistant Surgeon, Bristol Royal Infirmary; Lecturer on Physiology University of Bristol. Price, $7.00, cloth, net. New York: William Wood & Co., 1915.

AN Index of Treatment and an Index of Differential Diagnosis have already been published and have been accepted by the medical profession as works of unusual value, so that it is quite in the order of things that an Index of Prognosis should be brought out to supplement the earlier works. The principal aims of this work are: (1) To set the results, and particularly the end-results, of various methods of treatment in such a form as will enable the practitioner to obtain a fair, unbiassed, reasoned opinion as to the prospects of securing for his patient permanent relief, and also to note the risks of such treatment. (2) To furnish data by means of which, apart from the question of treatment, one may seek to arrive at an accurate forecast of what will probably happen to the individual patient. In the execution of the plan Dr. Short has been assisted by an able band of collaborators, and the scheme has been carried to a successful issue. The task has been by no means light, involving a great deal of tedious investigation. Of course the main reliance in compiling this work has been placed on statistics, as such is the only satisfactory way of expressing end-results. Statistics have been gathered from several sources and have been carefully revised so as to admit of as little error as possible. The result fully justifies the effort made necessary to render the work authoritative, and it should for some time to come supply a ready and reliable book of reference with regard to prognosis.

THE THEORY OF PSYCHOANALYSIS. By Dr. C. G. JUNG, of Zurich. Nervous and Mental Disease Monograph Series, No. 19. Price, $1.50. New York: The Journal of Nervous and Mental Disease Publishing Company, 1915.

DR. JUNG has been closely connected with psychoanalysis for many years. This monograph of his is intended not only to show the evolution of the subject since it was originated by Freud and Breurer; but it also offers free criticisms, and certain more or less original formulations which, he says, "Present the observed facts more adequately than is the case in Freud's method of statement." The subject matter was presented originally in the form of Lectures to Physicians at Fordham University, in September, 1912, in an "Extension Course." As arranged in chapters, the titles are as follows: Consideration of Early Hypothesis; The Infantile Sexuality; The Conception of Libido; The Etiological Significance of the Infantile Sexuality; The Unconscious; The Dream; the Content of the Unconscious; The Etiology of the Neuroses; The Therapeutic Principles of Psychoanalysis; and Some General Remarks on Psychoanalysis. As an example of change in the theory of psychoanalysis, since first promulgated, the writer recalls the fact that the doctrine that hysteria, as well as other neuroses, has its root in the so-called traumata of earliest childhood, was abandoned by Freud himself about fifteen years ago and replaced by a totally different one. Also the method of analysis beginning with symptoms is not used by the regenerated psychoanalyst of today. Again the term "libido," as used by this author, has broadened in significance from that of sexual craving, simply into the more general sense of every passionate desire. We mention these things more especially for the critics of psychoanalysis, in the hope that a careful study of Jung's book may lead to the reading of other recent literature on the subject, and ultimately to a change of heart towards a subject which is doing more in the advancement of our knowledge of the psychoneuroses and certain psychoses than anything else at the present day. The author states that "Wherever really sincere and thorough investigations have been carried out it has been possible to corroborate his (Freud's) observations." But, "Excessive sexuality, sexual abuse of children, or very early sexual activity in childhood, were later on seen to be of secondary importance." The trauma "owes its efficacy to the nature of the soil upon which it falls." Jung strongly advances the energic theory of the libido and says that the task of psychoanalysis is "to search for that hidden place where the libido dwells, and where it is as a rule inaccessible to the patient." Psychoanalysis is a method which "discovers those places or functions where there is too little or too much libido, and restores the just proportions." We should like to quote further and make an analysis of the book, but lack of space prevents. The book is interesting and valuable. It is a slight deviation from pure Freudism, perhaps, but the author disclaims that his criticisms are a "falling away" or a schism. On the contrary his object has been "to open a path towards the scientific treasures of psychoanalysis for those who have hitherto been unable to possess themselves of psychoanalytic methods, whether through lack of practical experience or through distaste of the theoretical hypotheses."

NURSING AND CARE OF THE NERVOUS AND THE INSANE. By CHARLES K. MILLS, M.D., Professor of Neurology in the University of Pennsylvania; Neurologist to the Philadelphia General Hospital. Third Edition. Revised by the Author, assisted by N. S. YAWGER, M.D., Instructor in Neurology in the University of Pennsylvania; Assistant Neurologist to the Philadelphia General Hospital. Price $1.25. Philadelphia and London: J. B. Lippincott Company, 1915.

THE first edition of this little book for nurses appeared in 1887 and contained at that time rather fuller suggestions and directions for nursing nervous conditions than most of the manuals on general nursing. It comprised Dr. Mills' lectures on this special subject, to the nurses of two training schools, and contained information as to the care of nervous patients, and also as to the use of massage and electricity. In the present edition new material has been introduced on epilepsy, insanity, and fibrosis, and a chapter on hydrotherapy. The aim of the author has been, he says, "to recall facts regarding nursing obtained by experience." The book if used by attendants on insane patients will be found of most value when studied in connection with more general works on nursing.

RADIOGRAPHY, X-RAY THERAPEUTICS, AND RADIUM THERAPY. By ROBERT KNOX, M.D. (Edin.), M.R.C.S. (Eng.), L.R.C.P. (Lond.), Hon. Radiographer, King's College Hospital, London; Director, Electrical and Radiotherapeutic Department, Cancer Hospital, London; Hon. Radiographer, Great Northern Central Hospital, London; Captain R. A. M. C. (T.) 4th London General Hospital (in charge of *X*-Ray Department). With sixty-four plates, two hundred and forty-six illustrations in the text, and a frontispiece in color. Price $8.00. New York: The Macmillan Company, 1915.

THE recent advances in our knowledge of radiotherapy have necessitated a complete revision of our previous ideas, and, consequently, the scrapping of most of the older textbooks. The English practice in radiography is very well presented in this volume, which is sufficiently comprehensive to enable anyone to develop a satisfactory technique, to produce good radiographs, and, after some experience, to interpret them fairly. The directions for treatment are also sufficient to enable an intelligent worker to do such things as can be accomplished by radium and the *x*-rays. The first portion of the book is given up to a very full description of the technique of the production of Röntgen rays, the equipment, the construction of tubes, the apparatus, and the methods of localization, and, finally, an interesting series of studies of various pathological lesions, chiefly in the bones. A good deal of space is also devoted to lesions of the thoracic viscera, especially in the diagnosis of aneurysms. Here there are brought out a number of points with which the American radiographer would do well to familiarize himself. The use of the fluorescent screen is insisted upon for a proper study of gastrointestinal lesions; yet there are a great many laboratories in this country in which no such screen is available. The last portion of the book on the therapeutic use of radium and *X*-ray is very properly conservative, as might be expected from one who has given much treatment and has followed the cases and seen the disease recur and the patients die. The photomicrographic illustrations of the changes produced in tumors and other tissues by radiation are very satisfactory. A useful glossary completes this extremely practical volume.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Fortieth Annual Meeting, Held at White Sulphur Springs, West Virginia, May 18, 19, and 20, 1915.

THE PRESIDENT, DR. THOMAS J. WATKINS OF CHICAGO, IN THE CHAIR.

(*Concluded from page 377*)

Primary Cancer of the Female Urethra: Plastic Work and Late Results.—Dr. H. S. CROSSEN of St. Louis said that, in order to determine the proportion of cases of cancer cured by operation, he had tabulated the operative cases found in cursory examination of the literature as follows: Cases subjected to radical operation, 25; cured (3 years) 8; probable cures (2 years), 3; recurrences known, 8; results not shown, 6. Thus it would sems that of the treated cases about one-half were cured. That was a very encouraging showing, considering the fact that lymphatic metastases took place directly in the deep glands within the pelvis. On account of the direction of the lymphatic drainage, the first metastases made recurrence certain, for the affected glands were beyond reach. In the series tabulated, some of the operations were not very extensive, the operators removing only one-half or two-thirds of the urethra. The large proportion of cures was probably due to the fact that in the urethra an area of irritation caused symptoms very early, and thus led to investigation in diagnosis and radical treatment while the disease was still in a comparatively early stage.

Dr. LEWIS S. MCMURTRY of Louisville thought the chances for a radical operation being successful were very much endangered by the natural delay in making a diagnosis. He ventured to say, that nearly all cases reported had been primarily operated upon as urethral caruncle, and the malignant character of the growth had been lost sight of until the patient had been under treatment for caruncle for some time, and then failure of this treatment and extension of the growth had impressed the surgeon with its true character. If those cases were taken very early, and diagnosed promptly, the same as cancer in other portions of the genito-urinary tract in women, the results would be much better from complete excision.

Dr. FREDERICK J. TAUSSIG of St. Louis stated if we included all cases where the history pointed very strongly to primary growth of the urethra and conditions at the time of examination showed a cancer involving the urethra and surrounding tissues, we would find the reports very much more favorable. He had occasion about three months ago to remove a small nodule from the urethra of a woman, fifty-three years of age, and his pathologist examined it a long time before he made up his mind it was not malignant. The epithelial proliferations in the urethra closely simulate early cancer, and he had the impression that probably a certain number of those cases that had been reported as cures were not really cancers.

Dr. JOSEPH BRETTAUER of New York City had had but one case of primary carcinoma of the urethra. He had seen several cases of carcinoma of the external genitals and had published a series of 5 cases. Carcinoma of the female urethra was the most dangerous and malignant of all carcinomata he had encountered. Every one of the cases he had published was operated radically. It was exceedingly difficult, if not impossible, to differentiate between early carcinoma of the urethra and urethral caruncle. It was more guesswork than anything else.

Dr. HIRAM N. VINEBERG of New York City stated that one of the cases reported by Dr. Crossen was one to which his name was attached, and he could vouch for the genuineness of that particular case. The specimen was examined by two good pathologists and both made the diagnosis of carcinoma. The woman after operation was free from the disease for three years. She was still free from recurrence, it now being ten years since the operation was done.

Dr. J. RIDDLE GOFFE of New York City related two cases on which he had operated, removing the urethra.

Dr. WILLIS E. FORD of Utica, N. Y., said his first case of primary cancer of the urethra was in a doctor's wife who lived in northern New York. The growth, which was about as large as a walnut, obstructed the passage of urine. He removed the urethra to such an extent that he thought he left but very little of it. He did a purse string, closed up, and the patient got retention of urine. The growth returned within six months. Since that time he had seen half a dozen cases, and with the exception of primary cancer of the clitoris, he thought it was the most rapidly fatal of all cancers he had ever seen or had had anything to do with.

Prolapsus of the Uterus.—Dr. HERMAN J. BOLDT of New York City stated that before deciding upon a particluar operation, it was well to consider whether future offspring was desired by the patient or not. From his point of view, it was perfectly justifiable to give the patient an opportunity to express her wish in that respect, and for them to consider in connection with such a wish the justifiability of granting it. The patient should have a voice in this matter. A simple vaginal hysterectomy for prolapsus of the uterus should have no place in their domain of work, since by it a vaginal descensus could not be cured. During the child-bearing period and the uterus in not more than the second degree of descensus, so that perhaps the cervix came down nearly to the vulva, he knew of no surgical intervention which answered an equally good purpose as a ventral suspension by the round ligaments *á la* Gilliam, combined with a plastic operation upon the pelvic floor, but not with too much narrowing of the vaginal canal. If properly done, a permanent cure would result in ninety per cent. of the cases, unless a subsequent pregnancy should undo the result of the operation. Patients who had a marked descensus, partial prolapsus, and complete prolapsus, in whom no further offspring was expected, might be treated by a vaginal operation with the expectation of getting a good result. A properly executed vaginal operation would overcome the displacement of the uterus and vagina, as well as any existing cystocele and rectocele. Personally, he preferred the radical vaginal fixation. The technique must necessarily vary with the individual case. In patient who had a complete procidentia of the uterus and vagina, and of which no further use of the vaginal canal was to be made, as very old women, or widows who did not expect to marry again, they could do an operation which would guarantee an absolute cure, namely, a total extirpation of the uterus and the vagina, columnizing the vaginal tract by circular sutures, an operation that was comparatively simple, and an absolute guarantee as to permanent results.

President's Address: "What Has the American Gynecological Society Done for Gynecology?"—Dr. THOMAS J. WATKINS of Chicago gave a review of 683 papers which had appeared from time to time in the 39 volumes of Transactions of the Society, and said that all of those contributions were valuable additions to gynecological literature.

A Precise Method of Choosing a Time for Operation in Pelvic Inflammation of Tubal Origin.—Dr. FRANK F. SIMPSON of Pittsburgh said it was an axiom in pelvic and abdominal surgery that, in competent hands, almost all infections formerly thought imperatively to demand surgical intervention even at the height of the disease, could be easily converted into conditions suitable for elective work. Practically the only exceptions to this rule were traumatic injuries, intestinal obstruction, perforative lesions of hollow viscera, and some cases of appendicitis and of tubal pregnancy. In his judgment the questions of mortality, or post-operative morbidity, and the smoothness of convalescence depended almost entirely in competent hands upon a strict adherence to the following postulates: 1. The patient should have recovered from her acute illness and should have regained a satisfactory margin of reserved strength. 2. The temperature should not have risen above normal a single time for a minimum period of three weeks. 3. There should have been no marked or persistent rise of temperature following a careful bimanual examination. 4. The inflammatory exudate surrounding the focus of infection should have been completely absorbed. No one of sound judgment would think of choosing as a subject for elective operation, a patient acutely ill from pneumonia, typhoid fever, scarlet fever, etc. The same principle applied to those suffering from the effects of bacterial poisonings generated in the pelvic structures. As pelvic infection of tubal origin rarely killed, most operations for its relief should be done only at the quiescent or elective period. The temperature should not have arisen above normal a single time for a minimum period of three weeks. This was an em-

pirical rule based upon the belief that it frequently required a minimum period of three weeks of absolutely normal temperature for Nature to destroy all bacteria and to restore the affecteed tissues to the normal. All operators of experience knew the serious technical difficulty confronted when intestinal wall and other structures were still infiltrated and friable—stitches torn out, raw surfaces could not be folded in, peritoneum could not be glided over denuded areas, and serous and bloody oozing from infected surfaces tempted one to the use of drainage and invited adhesions, intestinal obstruction, fecal fistula, hernia, etc. An analysis of the first 456 of his series of 856 consecutive abdominal sections was made in a paper read at a meeting of the society in 1905. A study of the records of 400 additional abdominal sections done in part or in whole on account of inflamed tubes showed that there had never been an exudate, or that the exudate had been completely absorbed, 340 times with only one death and without postoperative complications as a consequence. An exudate of variable extent was present at the time of the operation in 60 cases. In 44 instances it was slight. In this series there were 2 deaths and 20 others had a stormy convalescence. In the remaining 16 cases, there was a marked exudate. Two of these patients died. The remaining 14 were seriously ill after operation. Where the exudate was marked at the time of operation, the death rate was 12½ per cent. Where the exudate was slight, the death rate was 4.6 per cent. Where there was no exudate the death rate was less than 1/3 of 1 per cent. It was evident that in the series of cases analyzed a more rigid adherence to the four postulates given would have resulted in a material reduction in the death rate. It was clear, therefore, that the only safe time to operate was when the patient had a fair margin of reserved strength, when she was not acutely ill, and absolutely no inflammatory exudate would be opened into the free abdominal cavity.

Dr. Joseph Brettauer of New York City said when we went back ten or fourteen years and compared the sense contained in the papers read at that time with the sense of the paper read to-day, we marvel at the discrepancy. He had heard members of the society read papers the gist of which was to operate as soon as they saw the patient, exudate or no exudate, if they could remove the tube. If they could not pack the entire pelvis with iodoform gauze and drain, they said it was preferable to remove the diseased organ. He did not remember the exact death rate after this interference. He had never done anything else except to follow the practice as outlined by Dr. Simpson. Not only did we minimize the death rate by conservative measures, but we decreased the number of patients where we found an operation necessary. Many of these patients did not need an operation in the case of purulent collection in the tubes or in abscess formation. The pathological and anatomical end results were a tubo-ovarian cyst, a closure of the tube with adherence of the ovary, breaking through of the follicle into the tube with a resulting tubo-ovarian cyst, which, in a great many instances never required an operation because there were no symptoms, and it was detected often by mere accident.

Dr. John O. Polak of Brooklyn, N. Y., said he applied the plan that had been outlined by the essaylst eight or nine years ago and followed it to the degree of overconservatism, but he thought he had saved hundreds of organs. He had been surprised in opening these cases to find how perfectly the pelvis had regenerated, not only as regards functional ability, but as to the actual possibilities. For instance, he had seen cases after three or four years absolutely clear up and pregnancy had occurred after mixed infection. Such a paper as this should be brought to the attention of surgeons and general practitioners as we could appreciate what Nature would do in cases of pelvic inflammation.

Dr. Thomas J. Watkins of Chicago said that he agreed with Dr. Simpson, with the possible exception that sometimes it seemed of value to operate very soon after these patients had acquired a complete immunity to the infection. They had taken the temperature and the white count with the idea that there would be some advantage in operating before the adhesions became thoroughly organized. They had made some observations on this, and it was quite safe to conclude that the increased amount of raw surface resulting from operating as soon as immunity had occurred was so much greater than the raw surfaces which remained after operating, if the adhesions had become somewhat organized so as to make the advantage in favor of the later operation. The number of adhesions encountered in operating at an earlier period were undoubtedly greater, many of them being absorbed more readily than they were during a later period.

Dr. Dougal Bissell of New York City said he was in perfect accord with everything contained in this paper, and his conclusions regarding the subject dated back several years, the result of an unhappy experience in the Woman's Hospital when he was an intern. The mortality from persistent operations upon cases of acute pyosalpinx and pelvic inflammations was very high, and with increased experience he refused to operate on these cases, and in following that practice his mortality had been very low ever since.

Dr. J. Wesley Bovee of Washington, D. C., said as soon as Dr. Simpson told him of his method of treatment, he adopted it, and in conjunction with the leucocyte count, he had followed it very thoroughly with the exception of two classes of cases. In the tubercular cases he would operate at once. In these one could hardly expect nature to bring about a successful cure. In the other class he had markedly gone afield, and that was in the acute gonorrheal cases. He was not yet ready to report on his work in this regard. He had not seen the abdominal conditions after this procedure, but he had sterilized the vagina and vulva with iodin and the interior of the uterus by injecting it, the vagina and the Fallopian tubes, opening the abdomen, separating adhesions, painting all raw surfaces thoroughly, but not normal peritoneum, with iodin, putting in drains down to the cul-de-sac before he opened the abdomen, and then draining through the cul-de-sac of Douglas, and he had been pleased with the results. He had done this in the acute cases with a temperature of 103.6°. For the cases that were more subacute and with lower temperature he did not think the plan was feasible.

Dr. H. S. Crossen of St. Louis said one had more or less difficulty to determine when to operate upon a mass that had passed the acute stage and was in the subacute or chronic stage. It might be two months or two years since the acute infection took place, and it was a question whether to do an abdominal operation or not. We could often determine a gonorrheal infection, and it was safe to operate within three months afterward or two months after sterilization. If it was a streptococcus infection, it was never safe. Streptococcic masses were in many instances found self-sterilized. On the other hand, there had been other cases reported in which the infection had lasted as long as six or even twelve years.

Some Points in the Diagnosis of Ectopic Gestation.—Dr. George Tucker Harrison of Charlottesville, Va., said the diagnosis of ectopic gestation often presented few difficulties, but at other times, as all gynecologists must admit, there was no problem in the whole range of gynecological diagnosis so difficult as the establishment of this pathological condition. One error of diagnosis must be carefully guarded against, and that was to assume that the case was one of hematocele, when in point of fact it was a tubal pregnancy, located in Douglas' cul-de-sac. Such a case he reported some years ago. The deep situation of the fetal sac in Douglas' cul-de-sac and the rough uneven surface above stimulated the characteristic phenomena of an accumulation of blood in the posterior pelvic cavity. Before he saw the woman she had suffered a chill, followed by fever. When she came under his observation the temperature was 105°. His diagnosis was hematocele which had become infected. A posterior colpotomy was performed and to his surprise, on entering the cavity with the finger a fetus of four months was discovered. Fearing a fatal hemorrhage the placenta was not removed, but treated by continuous irrigation. The patient ultimately made a good recovery. To mistake uterine pregnancy, the uterus being in a position of lateral flexion, for a tubal pregnancy would seem to be utterly unjustifiable, and yet such mistakes had been made by some competent men.

Dr. Arthur H. Curtis of Chicago said in the diagnosis of tubal pregnancy, also in certain instances of uterine pregnancy, in which it was difficult to ascertain the exact condition of affairs, he wanted to mention possible enlargement of one ovary. This was due to the presence of a corpus luteum. The enlargement of the ovary due to the presence of a corpus luteum in the case of tubal pregnancy was no greater oftentimes than was that in association with normal menstruation, but it was great enough so that the ovary was noticeably

enlarged and felt about the size of double that of the normal.

Dr. PHILANDER A. HARRIS of Paterson, N. J., said one should not place too much reliance on the physical examination of the pelvis in any stage of pelvic congestion, because he did not know of any pathological state in which one would find a greater variety of conditions existing, owing to the fact that when we had ectopic gestation to deal with it was likely to present varied conditions and symptoms in different patients. He had come to think therefore that the important thing we must do was to get at the primary history. We needed this, as well as the initial symptoms of ectopic gestation, to make a diagnosis of the condition.

Dr. HERMAN J. BOLDT of New York City said the correct diagnosis of ectopic gestation was by no means always easy. A condition that had given most trouble and which made the diagnosis difficult had been that in which we had a virulent inflammation of the adnexa. He knew of no condition, so far as the history and the objective symptoms went, which was so likely to lead to error in diagnosis as that.

Types of Carcinoma of the Uterus.—Dr. LAWRENCE W. STRONG of New York City said endometritis did not appear to be an etiological factor in carcinoma uteri. The condition itself was ill-defined and no causal relationship had been proved. It was customary to call a carcinoma which adhered to the glandular form an adenoma destruens and to speak of the secondarily solid one as adenocarcinoma. This led to the idea that an adenoma destruens was not a carcinoma in the true sense, while in reality it was a carcinoma from the start. Adenocarcinoma was a rather poor term because it suggested a combination of adenoma and carcinoma. Carcinoma glandulare was the best designation for this type. Benign adenomata of the uterus did not exist except in the form of adenoma polyposum. Glandular tumors not on the surface were carcinomata from the start. The general teaching of the present was that tumors grew exclusively from their own cells, never by the conversion of the normal cells at the margin or elsewhere into tumor cells. In looking over the figures of the hysterectomies at the Woman's Hospital, New York, in the last three years it was somewhat surprising to find 86 cases of cervical carcinoma as against 46 of the body, roughly, 2 to 1. This had no broad significance, for the operability of corporal was far greater than collum carcinoma. However, the proportions found in his laboratory suggested certain things. It might be that in examined cases some carcinoma of the body were overlooked on account of their lesser accessibility to the eye. Then, also, accidental microscopic discoveries of corpus carcinomata were more frequent than collum carcinomata. It might be that the corpus carcinomata would appear to have an increased prevalence in the future when curettings were more systematically examined. A wedge-shaped excision including normal tissue was to be preferred for a diagnostic specimen in suspicious cases of carcinoma colli. A frozen section was not desirable in collum carcinoma, since a suitable piece might be removed without anesthesia a few days prior to the operation, allowing careful imbedding. No likelihood of implantation metastasis would result in the few days intervening. The objections to frozen sections at operation in suspected collum carcinoma were those of frozen sections in general. In the case of curettings from the corpus, a frozen section should never be attempted. The tissue was too frail for manipulation and gross inspection was a reliable factor in interpretation.

Dr. JOHN G. CLARK of Philadelphia said as one realized the enormous changes the endometrium underwent during the twenty-eight cyclic days, the variations were so extreme and so closely simulated in many instances pathological processes, that the mere question of a hasty diagnosis while the patient was on the table by frozen section was a hazardous one, and he believed would do as much harm as good. Dr. Strong pointed out the importance of not laying too much stress on the frozen section, and that of itself was of great practical value to us.

Dr. FREDERICK J. TAUSSIG of St. Louis said in the cases at the Barnard Cancer Hospital in ten years they had had 150 cases of cancers of the female genital tract. Of that very large percentage, full three-fourths or four-fifths of the cases were invariably late cancers. They did not find more than two or three cases in which the tumor lay primarily in the corpus or body of the uterus. They had had cancers of the cervix which had gradually extended up into the fundus, but of cases that started in the fundus and made a large tumor and broke into the peritoneal cavity, they had not had more than two or three cases.

Dr. HERMAN J. BOLDT of New York City said the unreliability of frozen sections was brought home to him by a well illustrated example three or four years ago when he suspected the presence of carcinoma, and he sent a piece of the tissue to the laboratory at the time and waited for the report. The report of the laboratory came back to the effect that he had a benign condition to deal with, and the result was he did not do anything except the plastic work which was necessary. A week or ten days later the laboratory sent a report with an apology for having made an error in diagnosis, based on the fact of the frozen section, and that it was not reliable. The condition was malignant and he had to do a more difficult operation than he would have done at the start.

Technique and Experimental Application of Hard Rays for Deep Roentgen Therapy.—Dr. LEWIS GREGORY COLE of New York City said in the treatment of desperate cases of cancer which were bound to die, he had increased the amount of the highly penetrating screened ray until he was giving twelve to sixteen Hampson units or three to four times the standard erythema doses through each port of entry. When these large doses were given care must be observed that the areas should not overlap, and scar tissue should be protected from getting the full force of the ray. In one case which had been diagnosed as mediastinal sarcoma he gave twenty treatments through twenty ports of entry, each one being 3½ inches square on the surface. Each treatment was given with an 8-inch parallel gap, 10-ma. circuit, 6 inches distant from the skin, 4 minutes time, dose 12 to 16 Hampson units. With the old type of tube and without screen or cross-fire, six Hampson units was about the limit that could be applied to the skin. If this were directed to a tumor 6 inches below the surface only, about one-sixteenth of the energy would reach the tumor, therefore the tumor would receive about 3.8 of one Hampson unit. With this mediastinal tumor 12 to 16 Hampson units measured beneath the filter were applied to the surface every day except Sunday. One-fourth of that or an average of 3½ Hampson units was applied to the growth itself at each treatment, and twenty ports of entry were employed for each series; therefore 3½ times 20 or 70 Hampson units were applied during the first series, and by the time the first series was completed the skin had so far recovered that he repeated the procedure, beginning the second series within ten days after the first series ceased. With each dose of this series about twelve Hampson units reached the tumor mass. Twenty more exposures were given, making sixty Hampson units, making a total of 130 Hampson units applied to the tumor itself, more than 150 times the amount that could have been applied without the high penetration rendered possible by the Coolidge tube, the screen, the cross-fire method of exposure. Two months later a third series of twenty treatments was given, making a total of 190 Hampson units applied to the tumor mass as compared with about one or one and a half Hampson units that could have been applied to them with the standard tubes without the screen or cross-fire.

Roentgen Therapy in Uterine Fibroids and Uterine Hemorrhage.—Dr. GEORGE E. PFAHLER of Philadelphia drew the following conclusions: (1) Roentgen therapy must be looked upon as a very efficient adjunct to the armamentarium of the gynecologist, and while the ray should be applied by the Roentgenologist we should at the same time work hand in hand with the gynecologist. (2) Deep Roentgen therapy stops the hemorrhage associated with uterine fibroids. This is followed by a gradual disappearance of the tumor. This atrophic process may extend over several years and continue long after the cessation of treatment. (3) The treatment of metropathic hemorrhage is almost uniformly successful. (4) Uterine hemorrhage occurring at the menopause, when not due to malignancy, will usually respond very quickly. There should be an increase in weight and an improvement in the blood condition following the treatment, and when this does not occur suspicion of malignancy should be aroused. (5) Some good results can be obtained in inoperable carcinoma. The deep Roentgen therapy should be especially recommended as post-operative treatment in call cases.

Dr. HOWARD C. TAYLOR of New York City said he would like to know if, in the treatment of idiopathic hemorrhages which occurred in young women Dr. Pfahler was sure there was not some permanent injury

done to the ovaries. It would seem to him that with an organ as delicate as the ovary there were a certain number of cases in which pregnancy had subsequently taken place, and on account of some injury the offspring had not been as perfect as it would be in other instances.

Dr. Joseph Brettauer of New York City said as to the future of young girls in whom he had tried the *x*-ray treatment, the result had been beneficial. There was no cessation of menstruation, but in one case there was delayed menstruation. Instead of menstruating every two weeks, the girl menstruated every five or six weeks in very moderate amount.

Dr. John G. Clark of Philadelphia said he was definitely in favor of *x*-ray treatment in women over forty, and particularly those approaching the menopause. As Dr. Pfahler had said, these cases with hemorrhage of the menopause had been singularly satisfactory cases to treat, and these patients had been extremely grateful for having been saved the hazard of an operation.

Dr. Thomas J. Watkins of Chicago said he would like to ask Dr. Pfahler if there was any evidence to show that the *x*-rays produced intraperitoneal adhesions.

Dr. Pfahler said that, in answer to the question of Dr. Taylor with reference to possible subsequent injury to the ovary, he confessed that he could not answer it absolutely. He knew, however, that the ovary, like the testicle, had wonderful power of regeneration. With regard to Dr. Watkins' question concerning intraperitoneal adhesions, he did not know that any intraperitoneal adhesions would be produced by the *x*-ray, but according to investigations that had been made, many of these intraperitoneal adhesions had become absorbed as the result of *x*-ray treatment and the uteri had become freely movable.

Bladder Function after Confinement and After Gynecological Operations.—Dr. Frederick J. Taussig of St. Louis said while there were gradations of deficiency in bladder function after confinement and operation, we could for practical purposes divide patients into four groups: (1) Those who showed at such times no appreciable difference from normal micturition. (2) Those who while able to void urine spontaneously did not for a day or two empty their bladders completely. (3) Those who required catheterization one or more times in the first few days, but were then able to void urine without further trouble. (4) Those with prolonged interference of bladder function, who, even when finally able to void urine after several days of catheterization, were able to expel only a part of the bladder contents. The character of the operation, the form and amount of the anesthetic, the age of the patient, the nervousness of the individual, and the degree of sensitiveness of her bladder mucosa, were all factors that to a greater or less extent came into play in producing urine retention, and the object of the gynecologist should be to regulate his therapy as far as possible in accordance with the probable factors in his case.

Laboratory Diagnosis of Chronic Infections of the Urinary Tract in Women.—Dr. Arthur H. Curtis of Chicago drew the following conclusions: (1) Chronic infections of the urinary tract can be best diagnosed by one who is actively engaged in clinical work, including cystoscopy and in laboratory study. Careful correlation of clinical findings and laboratory methods, with extensive modifications in cultural technique to meet individual cases is essential. (2) The source of even small amounts of pus in the urine should be investigated; the place of its formation should be definitely localized through the assistance of ureteral catheterization. (3) Persistent pyuria in the absence of a gross bladder lesion is almost invariably due to kidney disease. (4) In those frequent cases of bladder irritability which yield clear, bacteria-free urine, cultures from the traumatized ureteral canal, or from the introduction of a probe into Skene's ducts, may demonstrate the cause of infection. When bacteria are widely scattered or grow with difficulty, a mixture of the urinary sediment with blood followed by making a large number of ascites-blood agar tubes, of high dilution, result in conditions favorable for the development and isolation of the bacteria present. (5) Experience teaches that the chief lesions in urinary tuberculosis are usually renal. In obscure cases laboratory diagnosis is facilitated by the use of potassium iodide, tuberculin, kidney massage, limitation of liquids, repeated examinations of fresh specimens after high power centrifugation, Petroff's cultures, and the injection of a series of medium sized guinea pigs. (6) There is seemingly a tendency to put undue stress on functional urinary tests at the expense of careful routine examination.

The Advantage of Kelly's Method of Cystoscopy in Women.—Dr. Hiram N. Vineberg of New York City said Kelly's method of cystoscopy was so easily learned and so free from errors in interpretation, that it formed the method *par excellence* for the gynecologist, who had neither the time nor the vast experience necessary to become an expert in the use of the prism cystoscope. Further, in addition to being an easy method of diagnosis, it formed at the same time a ready means of making topical applications directly to the diseased areas and for the removal of foreign bodies and small growths.

The Use of the Galvano-Cautery Knife for Excision of Mammary Tumors for Microscopic Diagnosis.—Dr. J. Wesley Bovee of Washington, D. C., said shortly after installing the Downe's electrothermic angiotribe in 1903, he began experimenting with it in the treatment of the uterus and of the breast. For galvanocauterization of the advancing cervical cancer, he devised a cooling vaginal speculum that had proven very efficient and in breast tumors localized and only suspicious of malignancy he applied the galvanocautery for excision of the growths, or removal of portions of doubtful tumors for microscopical examination. In this work carried out in many cases he had found but one objection to it when properly used. This consisted of the slowness of the cautery knife when the breasts had been large. This led him to change the technic somewhat. To economize in time he adopted the plan of cutting the tissues for a short distance with a sharp knife, and with the flat sides of the cautery knife, immediately sealing to a considerable depth the sides and bottom of the wound. The use of the knife was again resumed to be promptly followed by the cautery as before. This process had been continued until the tissue desired was entirely removed, leaving behind a crater with charred boundaries. The hot oil that was fried from the tissues during this procedure was taken up promptly with small pledgets of cotton of gauze in the grasp of forceps and at once discarded. The wound was now covered carefully and the report of the microscopical investigation awaited. If the tissue was reported to be malignant a radical operation was at once performed. If it was reported to be benign the surgeon might yet decide, from a consideration of the clinical evidence, to perform a radical operation. If the operation was not to be extended, the wound margins were trimmed of all cooked tissue and the proximal portions of severed milk ducts and the wound closed completely with sutures. The J. Collins Warren operation he had performed satisfactorily with the knife and cautery.

The Treatment of Pyelonephritis in Pregnancy.—Dr. Raleigh R. Huggins of Pittsburgh said experiments led to the conclusion that ascending infection reached the kidney through the lymphatics more frequently than was formerly supposed. If this was correct, much might be learned from a careful search for the primary focus. This might be found in the bladder itself. Owing to the intimate relationship between the lymph system of all abdominal viscera, and that of the kidney, the primary infection might lie in the Fallopian tubes, appendix or the gall-bladder. In severe cases the diagnosis was usually made without difficulty. The evidence of toxemia, high leucocytosis, pus in an acid urine, with the presence of colon bacilli in pure culture were symptoms which were most suggestive. When pain was a prominent feature, pleurisy, infection of the gall-bladder, salpingitis, or stone in the ureter or kidney must be excluded. There was usually a pronounced rise in the temperature and chills. If not contraindicated, cystoscopy with catheterization of the ureters had the same field of usefulness here as a diagnostic measure that it had in the non-pregnant. The important factor in the recognition of this complication of pregnancy was to remember that in the presence of the above symptoms it was the condition most likely to be found. He had been impressed that the treatment in some instances required careful judgment. The mild cases were usually self-limited and responded to rest, proper diet, and urinary antiseptics. Irrigation of the pelvis of the kidney should be done if the infection did not yield to simple measures. Severe pyelitis was always a danger for both mother and child, and if the clinical manifestations did not subside promptly under the above treatment, then one ought to consider nephrotomy or the interruption of pregnancy. When surgical measures were not employed in some manner, death not infrequently occurred.

Postoperative Renal Infection.—Dr. GEORGE GRAY WARD of New York City said that in many instances of obscure and apparently unaccountable elevation of temperature, with concomitant symptoms of septic absorption occurring later in the course of a postoperative convalescence, were cases of renal infection, and they were much more frequent than was formerly believed. In the majority of cases these renal infections were of hematogenous origin and were due to the colon bacillus. In studying the reports of cases of this disease one was struck with the frequency with which they followed some operative procedures. This was not strange when one remembered the probable causative factors and the mode of infection. The preponderance of evidence, the result of both clinical and experimental research, tended to prove that the large majority of such renal infections were hematogenous in origin, although some cases might be caused by an ascending infection, either by way of the periureteral lymphatics or by extension up the lumen of the ureter. There were three types of infection, depending upon the degree of virulence. They were: (1) Cases which were mild in character. The patient was not severely ill and yielded to the thorough flushing of the kidneys by the ingestion of water, formaldehyde, proper diet and rest. The virulence naturally varied according to the particular organism, the condition of the kidney, and the general bodily resistance of the patient. (2) Cases in which the kidneys contained numerous septic infarcts, and minute or microscopic foci which were superficially situated in the cortex of the organ. Decapsulation or incision with drainage usually resulted in recovery. (3) The fulminating type which was characterized by a profound toxemia, and which was rapidly fatal unless a nephrectomy was done. Fortunately this type of the disease was usually unilateral. If operation was necessary, nephrectomy should not be done unless there were indications for it, as shown by the appearance of the kidney. A decapsulation or nephrectomy with drainage was sufficient in many cases as shown by numerous reports, especially in the colon bacillus infections. He reported one case of severe colon bacillus infection which evidently first attacked one kidney and then the other, and in which decapsulation with drainage resulted in a complete recovery.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held at Rochester, Minn., June 9, 10, and 11, 1915.

DR. GEORGE E. ARMSTRONG OF MONTREAL, PRESIDENT.

The Incidence of Heredity As a Factor in the Causation of Goiter.—Dr. JOHN E. SUMMERS of Omaha read this paper. He said that heredity and variation could not be regarded separately. We had to consider first the probable cause of goiter, and then, if possible, apply the most generally accepted principles of heredity, as apparently evidenced in the common occurrence of goiter in several or many members of a family. Many observations pointed to the conclusion that goiter was caused by a toxin generated by a microorganism which was introduced in drinking water, and multiplied in the intestinal tract. The disease had been produced experimentally in man and animals, and in the Salmonidæ fish, and from these latter transmitted to animals. In the modern sense an infectious disease could not be inherited, but familial goiter, more particularly when the members of the family lived in widely separated neighborhoods, could, as must so-called hereditary syphilis, be explained as derived from the infective state of the parents, and was strictly an inheritance. Serological research in this disease, in the opinion of the writer, would extract a toxin showing, as in the Wassermann reaction, a latent stage of the thyroid disease. From an hereditary standpoint the disease, as passed down from parent to offspring, might not be the same in each, because elements determining the possibilities and types of growth in one offspring might be dominant and in another recessive (Mendel's Law).

Dr. ALBERT J. OCHSNER of Chicago said that when there was a reason for increased activity in the trophic conditions of the body, as for instance, during pregnancy, or when the bony skeleton of the female increased gradually, as at the time of puberty, and sometimes during other physiological conditions, we found a very distinct increase in the size of the thyroid gland. He mentioned an instance of a town in Switzerland, where the drinking wells were abandoned and thereafter the drinking water obtained from the side of the valley, which was composed of granite rock, with the result that the incidence of goiter was decreased in the children from 59 per cent. to 2 per cent., and he suggested that this 2 per cent. might be accounted for either by heredity or by the surreptitious drinking of well water.

Dr. CHARLES H. MAYO of Rochester, Minn., said that he considered heredity in goiter a subject worthy of consideration and that although in some cases this was very marked, it was not yet as important in America as in the goiter regions of Europe. He considered that the bacterial theory, as advanced by McCarrison, must be considered with the theory of heredity by presuming that various members of a family would be subject to the same infections. As the thyroid was a defense gland, its activity was increased by various infections and infections had a family tendency.

Acute Cholecystitis Complicating Typhoid Fever.—Dr. HOWARD A. LATHROP of Boston read this paper. He said that acute cholecystitis, due to the typhoid bacillus, was an uncommon complication of typhoid fever. He reported the case of a man moderately sick with typhoid fever during the fourth week, who had signs of perforation, and on opening the abdomen there was found a perforation of the gall-bladder that contained bile-stained pus, but no gallstones. The man made a slow but uninterrupted convalescence. Typhoid bacilli was probably present in bile in all cases of typhoid, but acute cholecystitis did not arise without some exciting cause such as biliary stasis of the cystic duct or irritation from gallstones, which had been found in about 20 per cent. of the cases. Bile possessed no antiseptic action upon pyogenic bacteria. Typhoid bacilli reached the bile through the circulation and not by direct ascension from the duodenum. The symptoms were the same as in any acute case, but they might be obscured by the general condition of the patient. This complication should always be kept in mind as a possibility. Many patients recovered spontaneously, but the presence of a gall-bladder tremor was an indication for operation in order to avoid future perforation.

Abscess of the Liver in Typhoid Fever.—Dr. A. E. HALSTEAD of Chicago reported this case. In a recent review of one thousand cases of typhoid fever from the records of the Cook County Hospital of Chicago, Dr. Halstead found not a single case of typhoid liver abscess. In 1911 Eberts reported one case of his own and collected twenty-nine from the literature. In reviewing the literature since 1911, Dr. Halstead had not found a single case. In the autopsy records of 1,200 fatal cases, reported by Holscher, twelve were found in which foci of infection were present in the liver. In the cases reviewed by Eberts, in only twelve of the thirty was the *B. typhosus* isolated. In four there was a mixed infection, and in only eight was a pure culture demonstrated. The author's patient was a man, aged 39. The patient had an ordinary attack of typhoid fever, of moderate severity. The temperature reached normal at the end of thirty days, and remained nearly normal during the succeeding twenty days. At the end of this time he was discharged from the hospital and returned to his home, still complaining of the pain in the right hypochondrium. After being home for one week, his distress became so great that he returned to the hospital. The temperature was about normal on admission, but the leucocyte count had risen to 22,000. The liver was still large and excessively tender on pressure. Diagnosis of abscess was made, and he was referred to Dr. Halstead for operation. An incision below the costal margin exposed the liver, on the superior surface of the right lobe of which an indurated mass, the size of a man's fist, was found. Incision evacuated about ten ounces of thick yellow pus. The abscess cavity was entirely surrounded by liver tissue. The gall-bladder lay a considerable distance from the cavity toward the median line and appeared to be normal. The cavity was drained in the normal manner. Recovery without any complications ensued.

Dr. CHARLES N. DOWD of New York said that in order to obtain the best results in dealing with cases of typhoid perforation the physician and surgeon must be in close association and that every case of typhoid fever should receive particular attention from both the medical and surgical interne. He did not believe that pain, tenderness, and rigidity were the characteristic symptoms of typhoid perforation, since if such were the case the condition would be more quickly diagnosed. He

called attention to three elements which added greatly to the difficulty of diagnosis of typhoid perforation, namely, the apathy of the patient, the limited outflow of intestinal contents, and the location of the perforation, usually in the ileum, deep in the abdomen. The apathy of the patient was self-evident; the limited outflow of intestinal content was probably due to a very small perforation appearing in an almost empty intestine. The fact that the general location of the perforation was in the lower ileum well away from the parietal peritoneum was an important point. The parietal peritoneum had been shown to be supplied with sensory nerves, but the intestinal coating had nerves only from the sympathetic system; hence the explanation of the lack of pain in many perforations occurring in typhoid fever. Dr. Dowd believed that in order to obtain better results in such cases, a certain number of patients, even though they did not show severe symptoms, should be operated on for the purpose of diagnosis.

Dr. L. L. McArthur of Chicago related some anomalies met with in the four cases upon which he had operated for perforation in typhoid fever. One of them was a case of suppurative peritonitis supposedly from typhoid perforating ulcer, but a perforated typhoid mesenteric gland was found. In another case he found a perforation of the ileum, twelve inches from the valve, and also a perforation on the anterior surface of the ascending colon. After fifteen days of satisfactory convalescence the patient developed a perforated typhoid cholecystitis; this patient made a good recovery. He advocated strongly drainage in all cases of laparotomy for typhoid perforation.

Dr. Howard Lilienthal of New York stated that in all cases complicated by distention, hemorrhage as well as perforation was to be feared. In cases of hemorrhage he suggested the use of blood segregation by ligation of the thighs; he claimed that a reduction in blood pressure of from 40 to 60 mm. of mercury could thus be obtained, but called attention to the fact that the patient must be carefully watched in order that the blood pressure may not fall low enough to cause syncope. He advocated the use of this method by the interne in all cases of hemorrhage while awaiting the arrival of the surgeon.

Dr. A. V. Moschcowitz of New York said that in hospitals frequently the burden of diagnosis rested upon the shoulders of the interne rather than upon the visiting physician and called attention to the fact that, as a rule, the interne was not very conversant with the symptoms or signs of typhoid perforation unless he had been fortunate enough to have served during an epidemic. He called attention to another point in hospital work, namely, the great amount of time lost in obtaining consent for operation, it frequently being impossible to gain this from the stuporous patient, and he advocated that consent for operation (should this become necessary) should be required from all patients of typhoid fever upon their admission to the hospital.

Dr. James F. Mitchell of Washington, D. C., reported a series of cases of typhoid fever at the Johns Hopkins Hospital during the year 1900, at which time there was a standing order throughout the medical wards that the resident surgeon as well as the resident physician should be called whenever a typhoid patient had pain in his abdomen. In this series there were seven perforations disclosed by laparotomy with three recoveries; there were a few instances of operation where no perforation was found. There was not a single case of perforation that went unoperated upon and the longest time which elapsed between perforation and operation was a little over twenty-four hours. Those cases which went to twenty or twenty-four hours were accompanied by hemorrhage and for this reason the perforation was obscured. He called attention to the fact that in those days there was usually too much interference and that he believed that when operation was necessary as little as possible should be done.

Dr. H. B. Delatour of Brooklyn reported the results in nine cases of operation in typhoid which had come under his personal care; five of these patients recovered. He also reported a case operated upon for acute cholecystitis, for which no cause could be found at the operation but from which a culture taken from the gall-bladder showed the typhoid bacilli, and the history subsequently obtained showed that the patient had had typhoid fever seven years previously. In regard to appendicitis occurring during typhoid, he stated that in his experience, where the appendix became involved in the early stages of typhoid it was seldom perforated, but where it became involved in the later stages, it was more apt to go on to perforation.

Dr. M. L. Harris of Chicago called attention to the fact that in cases of typhoid perforation the patient was suffering from an acute general infection as well as from an acute peritonitis, and recognizing this fact in his last two operative cases, he opened the abdomen as quickly as possible under local anesthesia, closed the perforation, left the abdominal cavity wide open, and placed the patient in a permanent bath, with the water in the tub and abdomen free to each other; both patients recovered.

Dr. John Bapst Blake of Boston emphasized strongly that in very sick cases the perforation should not be closed but should be left open, thus practically forming an enterostomy; this would diminish the general toxicity, decrease the intestinal distention, and compel abdominal drainage; it would also save a little time in the operation.

Dr. K. A. J. Mackenzie of Portland, Ore., reported a case of supposed typhoid perforation in a child of 8 years in which it was found that enlarged lymph nodes were responsible for the symptoms. These surrounded the appendix and together with that organ were removed. Three months later symptoms of acute obstruction developed and operation revealed an ileal intussusception which was relieved. During the last three years the patient developed symptoms of chronic intestinal obstruction and operation revealed a loop of ileum adherent by a thick band to the anterior abdominal wall; this band was divided and the patient recovered. The interesting point in this case was the fact that at the original operation the crisis took place immediately upon removal of the large typhoid lymph nodes. The speaker stated that he had operated in four cases of typhoid perforation with one recovery.

Dr. A. J. Oschner of Chicago called attention to the possibility of reinfection with typhoid bacilli from the gall-bladder, and reported a case. He recommended that in any case of acute cholecystitis during an attack of typhoid fever, good results would be obtained by placing the patient on exclusive rectal feeding, giving an ounce of concentrated predigested food dissolved in three ounces of physiological salt solution every four hours and the administration of large quantities of salt solution by proctoclysis.

Dr. Dean Lewis of Chicago reported a case somewhat similar to that mentioned by Dr. Mackenzie, in which the symptoms of acute appendicitis were found to be due to enlarged ileocecal lymph nodes. In this case the appendix was removed but the lymph nodes were left, and a blood culture made the following day showed the paratyphoid organism. In this case also the crisis immediately followed operative interference. He referred to another case in which the symptoms were supposed to be due to the appendix, but removal of this organ was followed by a recurrence of the attack, resembling a perforation of a duodenal ulcer or an acute cholecystitis. A blood culture showed the paratyphoid organism. The patient was sick for seven weeks with paratyphoid, recovered, and then had several attacks simulating gallstone colic, but these attacks were accompanied by little or no temperature and no jaundice A cholecystotomy was performed, the gall-bladder found white and thickened, no gallstones were found, and the bile appeared normal, but the paratyphoid organism was grown from a culture taken from the bile. Following drainage of the gall-bladder, Dr. Lewis said, the attacks had disappeared and the organism disappeared from the stools.

Dr. J. Ewing Mears of Philadelphia stated that in 1888 he presented a paper before the American Surgical Association entitled "The Propriety of Surgical Interference in Perforating Typhoid Fever Ulcer," and at that time only four cases were recorded in the medical literature, in all of which a fatal result had occurred. In this paper of twenty-five years ago attention was called to the value of making an artificial anus, to be relieved later by an operation, should the patient survive. The claims for this procedure were that it facilitated the free escape of fecal contents and gas, thereby adding to the quietude of the patient and securing rest to the intestines. He advocated that in all cases of operation laparotomy with the production of an artificial anus should be the method employed, and under the additional knowledge gained during the intervening years, he still held this opinion.

Dr. F. W. Parham of New Orleans reported a case of typhoid fever in a boy of eleven with interesting and

unusual complications. The perforation occurred in the third week of an atypical attack of typhoid. Laparotomy was performed and the perforation was closed by nature; there was some free exudate. Four days later a subhepatic abscess appeared which was opened and drained. Forty-eight hours later clonic spasms occurred in the right side, localizing trouble on the left side of the brain. Without anesthesia and with the patient presenting a pulse of 170 an osteoplastic flap the size of the palm of a hand was reflected and a piece of bone removed. A wet pia was found beneath the dura from which smears were made but no organisms were found.

Dr. HERBERT A. BRUCE of Toronto referred to a complication of acute phlegmonous cystitis of the urinary bladder appearing in typhoid in the fourth week which necessitated suprapublic drainage and later the removal of large pieces of mucous membrane from the interior of the bladder because of blocking of the tube. He also alluded to a case of perforated typhoid ulcer operated on eighteen hours after perforation in which a subphrenic abscess developed two weeks later, requiring operation and followed by recovery.

Dr. FRANCIS T. STEWART of Philadelphia reported 42 cases of perforation with 14 recoveries. The patients operated on within the first twelve hours gave 50 per cent. of recoveries. He called attention to the fact that many perforations occurred in the lower ileum, that is, in the pelvis, hence rigidity was often absent in the early stages, but tenderness might be elicited by vaginal or rectal examination.

Dr. JOHN B. ROBERTS of Philadelphia called attention to the possibility of volvulus complicating typhoid fever, and stated that he had operated in one such condition in which he was convinced that perforation was the cause of the symptoms and in which the patient recovered.

Dr. JOHN H. GIBBON of Philadelphia stated that at the Pennsylvania Hospital there was a rule that whenever a typhoid patient developed pain in his abdomen, the chief resident physician was called and a member of the surgical staff was always summoned first, before the medical chief was notified. In this way some delay was avoided. He called attention to one case operated upon by Dr. Harte in which one perforation was found in the appendix and three in the ileum; the patient had three distinct relapses after perforation, and yet recovered. Dr. Gibbon also cited two cases in each of which there were five perforations found at the time of operation.

Clinical Notes on Splenectomy.—Dr. H. Z. GIFFIN of Rochester, Minn., reviewed in a general way the clinical characteristics of fifty-eight cases of splenectomy in the Mayo Clinic since 1904. One of the patients was alive and well 8 years after operation. In this instance the history was analogous to that of splenic anemia, while the spleen showed pathologically a lymphocytic hyperplasia, not, however, with any definite evidence of malignancy. In this instance there was a clinical history similar to that of splenic anemia, while pathologically the spleen showed endothelial proliferation. Many types of splenomegaly were necessarily represented in this series and any classification of the cases was, of course, open to discussion and criticism. Seven patients with pernicious anemia have been operated on since August, 1914, with one operative death, two patients were at present in the hospital, while three of the patients showed marked temporary improvement. The series included one case of acute febrile non-septic splenomegaly which was analogous in its clinical course to Egyptian splenomegaly, and one case in which splenomegaly was associated with an extremely high eosinophile count. Splenic anemia was, in his experience, most favorable for surgical treatment. The operative risk was relatively low and the prospect for a return to normal health excellent. Removal of the spleen in non-gummatous splenomegaly and in anemia associated with syphilis, Dr. Griffin stated, had been attended with excellent results in two instances.

Pathology of Spleens Removed for Certain Abnormal Conditions of the Blood.—Dr. LOUIS B. WILSON of Rochester, Minn., read this report. The study, he said, was a continuation of a previous report which covered the pathological examination of 26 spleens removed at operation or autopsy in the Mayo Clinic between November 14, 1905, and November 1, 1912, from patients on whom a more or less positive diagnosis of splenic anemia had been made, and of two "wandering spleens" removed at operations within the same period. The present preliminary report covered the examination of 31 more spleens removed at operations between December 3, 1912, and June 9, 1915. Further study of the several groups would be reported later. The cases had been studied clinically by Giffin, whose grouping was observed in the abstracts of the pathological protocols given. Pathological analyses of 15 cases clinically diagnosed splenic anemia were given. The average age of the patients at the time of operation was 36 years. The average duration of symptoms was 32 months. The average weight of the spleen was 1,130 gramms. This was a little higher than the average weight (975 gramms) of the spleens reported in 1913. The average of the two groups was 1,045 gramms. Few of the specimens equaled the weight given by Lyon[5] who has stated that the average weight was 62 ounces (1,060 gramms). This discrepancy was probably due to the fact that the Lyon's figures were drawn largely from autopsy reports, while ours were from operative material, the spleen continuing to enlarge until death. In general the change in the shape of the spleen was not so marked as the change in size. In other words, the hypertrophy was evenly diffused except in those cases in which infarcts had occurred. The maintenance of the notch was important from the standpoint of clinical diagnosis.

Surgical Considerations of Splenectomy.—Dr. W. J. MAYO of Rochester, Minn., said that the safety of splenectomy depended on careful separation of the attachments of the spleen and the delivery of the organ without injury to the vascular pedicle. A longitudinal incision was made through the upper half of the rectus muscle, extended obliquely along the costal margin about an inch and one-half from it and up toward the ensiform cartilage. The longitudinal part of the incision might be carried down to any desired length. Adhesions especially over the upper pole were occasionally vascular. It was best to separate these vessels with the fingers as close to the spleen as possible. Sometimes the adhesions were so strong they must be divided by a cutting instrument. The bulk of the vascular attachments (vasa brevia) in the gastrosplenic ligament could be delivered with the spleen, the stomach being partly withdrawn from the abdomen before separating the ligament. In a large, adherent spleen the deep vascular connections might anastomose with the vessels along the spine and the crux of the diaphragm. These must be separated before the spleen could be eviscerated, hemorrhage being controlled by a carefully adjusted gauze tampon. The application of this gauze tampon temporarily to control bleeding from the deep attachments was very important as the success of hemorrhage could not be seen and controlled until the spleen had been removed. The tail of the pancreas, if present, should be separated from the splenic pedicle, its bleeding points ligated, and the gland dropped back. In three splenectomies the speaker had tied off a portion of the tail of the pancreas with the splenic pedicle without any harm resulting. Usually the vascular pedicle could be cleared and ligated in sections. The arteries should be tied first but all vessels should be tied before any portion of the pedicle was cut. If the pedicle was short, it might be grasped with elastic rubber-covered clamps, thus avoiding damage to attached viscera, such as the gastric wall, until the vessels could be secured. The two-forceps method of ligation was very satisfactory: two forceps were placed three-fourths of an inch apart on the pedicle and the spleen cut away without regard to back bleeding. A catgut ligature was thrown around the pedicle below the proximal forceps which was then loosened and the ligature tied in the compressed area, while the distal pair of forceps steadied the pair and prevents retraction. A second ligature made the pedicle secure. Closure of the splenic space was important if there was any oozing of blood. Compression with the temporary tampon would seal the smaller vessels in a few minutes but deep in the wound other vessels might require further treatment. With catgut on a small curved needle, the raw space beginning at the tied splenic vessels was closed as well as possible by catgut sutures which compressed the bleeding vessels. The mortality depended more on the condition of the patient than on the technical difficulties of operation. But 5 of the 57 patients subjected to splenectomy died in the hospital, and autopsy showed that two of these deaths were from preventable causes—hemorrhage and sepsis.

BLOOD TRANSFUSION.

INDICATIONS AND TECHNIQUE.

BY GEORGE I. MILLER, M.D.

BROOKLYN, N. Y.

THE paramount interest in the technique of blood transfusion in the past few years has stimulated me, in addition to a good many others, to focus my attention to this important subject.

It is my purpose, in this communication, to bring together the various methods of blood transfusion and briefly to allude to some contrasts between the complicated inaccurate and unscientific apparatuses of the past and that of the ideal simple devices of to-day.

From a study of the literature and from observations of the practice by different men, I have obtained certain impressions of many of the numerous methods of blood transfusion now in vogue.

In addition to the authorities with their respective methods, which will give a panoramic impression of the subject, I will refer to some of my own ideas and work on the subject in hospitals, in outside private practice, and in my office.

Periodically, since the knowledge of the circulation and the value of blood has been established, different clinicians have advised blood transfusion with the hopes of saving life, or to hasten a patient's recovery. As early as the days of Columbus, when there was no conception of anything like a circulation of blood, we find in the book of "Savonarola's Life and Times," published 1859-61, Vol. I, page 151, the nature of the means employed to attempt the prolongation of the life of Pope Innocent VIII, who died in the month of July, 1492. Every means of restoring his exhausted vitality had been tried in vain, when a doctor proposed to attempt his cure by means of a new instrument for the transfusion of blood. Two or three healthy young men were obtained who volunteered their blood to save the pontiff. The patient was bled and the blood which escaped was injected into the veins of the young donors; when the blood had circulated a short time the young men were bled and the blood was transfused to the veins of the pontiff. The donors died after the phlebotomy without saving the life of the patient.

Though transfusion was an ancient tradition a German surgeon, Jean Daniel Meyer, claimed in 1667 to have been the first man to perform the operation.

In 1615 Libavius advocated arterial transfusion by means of a silver tube passing from a blood-vessel of the donor to one of the recipient.

In 1665, Lower of Oxford bled animals to a condition of syncope and then resuscitated them by injection of blood from other animals.

The first authoritative description of a transfusion was done by Denis, professor of philosophy and mathematics in Paris, 1667. He injected ten ounces of lamb's blood and cured his patient. His fortunate experience was imitated with disastrous results until transfusion of blood was finally prohibited by law in France.

The early failures were due to disregard of the physiology of blood *per se* and to the use of cumbersome complex mechanical appliances.

In 1825 James Blondell of London bled dogs until pulse and respiration ceased, and proved conclusively that animals apparently dead could be resuscitated by transfusion at the end of three or four minutes, but that if the operation was delayed for more than five minutes, it proved of no value. Russel of Suffolk is said to have cured a case of hydrophobia by opening the veins of the patient, allowing blood to flow, and then transfusing the blood of several lambs.

The use of blood from lower animals was soon after found dangerous and abandoned for human transfusion.

The methods practised in the first half of the last century had a good many fatal results, so that three of the foremost surgeons at the time—Von Bergmann, Senn, and Da Costa—openly objected to blood transfusion and advocated physiological salt solution intravenously in its place, except in cases of poisoning by illuminating gas. Their expressed opinion acted as a temporary stay to the performance of the operation; but it soon became apparent that salt solution could not replace blood in every instance where living blood was essential. Normal salt solution does not contain the element necessary to the nutrition of the brain cells damaged by shock, nor does it contain red blood cells for patients that must be brought out of gas poison, nor fibrin ferments, nor fibrinogen essential for hemophilia, nor the protective substances that resist infection.

Blood transfusion therefore is essential as a surgical therapeutic measure when more red blood corpuscles are wanting to supply nourishment and oxygen carriers to stimulate the blood forming organs, to increase the coagulability of the recipient blood, or when a transfusion will tide a patient over an emergency in order that some other therapeusis may be of value.

Indications for Blood Transfusion.—Blood transfusion is a cardiac and central nervous stimulant. The operation must not be performed as a last resort.

Anemia.—1. Primary: Acute loss of blood in healthy individuals from traumatic, accidental, after operation, removal of tonsils, etc., puerperal, postpartum, placenta previa, after abortion or miscarriage. In menorrhagia, metrorrhagia, menopause, ectopic pregnancy, ruptured Graafian follicles,

*Read before the Surgical Society of Brooklyn, N. Y., April 1, 1915.

Chronic loss of blood in hemorrhage from gastric ulcer, typhoid ulcer, tuberculous ulcer, dysentery, hemorrhoids, epistaxis, pulmonary lesions, renal hematuria, from unknown causes.

2. Secondary: Tuberculosis, sarcoma, cancer, pellagra, anemia from unknown causes, splenic anemia, cirrhosis of the liver, malnutrition.

Cases of bad surgical risks are benefited before and during the performance of the operation.

Shock: Prevention and treatment.

Destruction of corpuscles in illuminating gas poisoning, pernicious anemia. (Begin in the early stage of the disease and give repeated small quantities.) Poisoning by coal-tar derivatives, by substances producing methemoglobin.

Pathological hemorrhage: Hemophilia, melena, neonatorum, scorbutus, purpura hemorrhagica, Henoch's purpura, obstructive jaundice with slow coagulation time, cholemia.

Obscure pathology: Idiopathic epilepsy, mental depression, chlorosis.

Toxic conditions: Bacterial: Rheumatic fever with malignant endocarditis hydrophobia; eclampsia, toxemia of pregnancy; tonsillitis with petechiæ and anemia; delirium from toxemia or severe hemorrhage; metabolic.

Contraindications.—1. Whenever hemolysis is taking place. 2. Severe infection in the cachexia of cancer. 3. Uremia. 4. Acute hyperthyroidism. 5. Diabetes.

In his latest book, on "Emotions," Crile says: "If all the brain of an animal be removed by decapitation its body may live on for at least eleven hours if its circulation is maintained by transfusion, while an overtransfused animal may live many hours, days even, after the destruction of the medulla."

By what method then is transfusion easily accomplished? There are six kinds of transfusions, with three successful methods:

1. Direct method by means of: (*a*) Suture of vessels. (*b*) By the use of cannula interpolated in the blood stream. (*c*) By the use of cannula bringing intima to intima.

2. Indirect or interrupted method: (*a*) Needle and syringe. (*b*) Receptacle, containing anticoagulants.

3. Combination of the direct and indirect method: Valve and syringe.

4. Auto-transfusion: the driving of blood from the periphery to the center, the heart, and brain in order to maintain circulation, *i.e.* bandaging limbs in post partum hemorrhage.

5. Reciprocal transfusion is the exchange of an equal volume of blood between patient suffering from a febrile disease and one who is convalescing from that disease, the blood of the convalescing being supposed to contain an antitoxin.

6. Peritoneal and subcutaneous injection of blood.

In the direct method of transfusion a vessel of one person is united to a vessel of another person by suture or tube.

Suture of vessels, bringing intima to intima, has been practised and described by Murphy, Carrel, and Guthrie. Its advantage is that vessels of different sizes can be united. Before attempting vessel suture it is essential for the operator to acquire laboratory experience to become familiar with technical difficulties which may arise before one could feel safe of carrying out a successful transfusion.

The method of interpolating a cannula in the blood stream is the procedure of Brewer and Leggett, who used glass paraffinized tubes.

The advantages of this method are the simple technique, and that it can be used in very small vessels. The objection to its use is production of emboli, as a result of trauma from the tubes, and as a result of back currents due to the uneven calibers of the vessels.

J. F. Corbett modifies this by the use of a gold tube, with or without rubber connections. This has the advantage of the glass tube in that it is less liable to injure the intima and is more easily retained. It accommodates itself to a wide range in the size of vessels.

The two-piece tube of Bernheim has the advantage over single tubes: it can be managed by two operators, while one half is inserted in the donor, the other half can be introduced into the vessel of the recipient. Donor and recipient can be prepared in different rooms, and afterward the donor is wheeled into the recipient's room, the two are placed in opposition, and the two halves of the cannula are joined.

The cannula method which brings intima to intima in contact was originated by Tansini, improved upon by Queirolo, again revised by Payr, and finally brought to our attention by Lepinasse and Eisenstadt. It is represented by the Crile method. This has been modified by Janeway, Ellsberg, Buerger, Soresi, and a number of others. In this method the blood vessel must be cuffed over the cannula. The operation is of a major character and difficult to perform.

The direct method generally necessitates dissection of the vessels for several inches; it is not as easily performed as the description of each method makes the impression on the student; it destroys the vessels used of both donor and recipient; it requires expert surgeons to perform the operation, and does not offer scientific accuracy as to the quantity of blood transfused.

Before a practical method of measuring the amount of blood flow was devised, the surgeon was compelled to rely upon clinical signs for an index of the amount of blood transfused. Blood pressure, pulse rate, appearance of the patient, time that the blood has or is supposed to have flowed, increase of homoglobin were his guides.

Having at our disposal several simple, safe, and accurate methods of measuring the amount of blood flow transfused, it is but natural that no one would continue to travel in the dark when brilliant searchlights are within reach.

The up-to-date method that deserves consideration is the rejuvenated indirect syringe cannula of Lindeman. Von Ziemssen reported numerous cases, over twenty years ago, in which transfusion was successfully employed by such a method. It consisted in having one operator thrust a needle through the skin into the veins of the recipient, while another operator performed the same action on the donor. Three glass syringes of 25 c.c. capacity were kept constantly in action, one being filled with blood from the donor, the other being emptied into the veins of the recipient, while the third was being washed out with sterile salt solution by a third person before being again applied to the needle in the donor's vein.

By this procedure Von Ziemssen was able to transfer any desired amount of unaltered blood and to measure it accurately. Moritz (*Münch. med. Woch.*, 1911, 58, 393) emphasized the advantage of

the method and introduced some improvements in the technique which facilitated the puncture of the vein.

Lindeman, two years ago, using the same principle, devised a set of cannulæ by the aid of which even small veins may easily be entered and the danger of wounding the intima is reduced. To Lindeman, therefore, belongs the credit for having Americanized the syringe method.

Those who have seen him do a transfusion must admit that all other methods hitherto in vogue are placed in perpetual shadow. The ease with which the syringe and cannula can be handled is impressive to all who know the difficulties and failures of all previous existing methods.

Although his syringe method appears simple, some of our able surgeons and physicians of manual dexterity claim that (1) It is not easily performed; that the cannula is frequently displaced from the vessels of both donor and donee, and that it is either pushed in too far, or being shoved back and fourth by the frequent application of the tip of the syringe. (2) The blood frequently clots in the syringe, unless it is rapidly transferred to the donee. (3) In the effort to displace the air from the filled syringe, a considerable quantity of blood is lost. (4) The syringes can be used again only after they are thoroughly washed, which necessitates an extra nurse for the purpose. (5) From twelve to twenty syringes are recommended, requiring an investment of $100. (6) The cannulæ must be flushed with salt solution to prevent clotting before the next syringe-full of blood is ready, thereby injecting an unnecessary quantity of useless fluid in the recipient. (7) The assistant must be as expert as the operator for the successful performance of the transfusion.

To overcome these difficulties experienced in the syringe cannula method, several physicians interested in blood transfusion, notably Hustin, Weil, Lewisohn, and Zingher have reverted to the abandoned practice used in the nineteenth century of adding various chemicals to prevent the coagulation of blood, such as carbonate of ammonia (10 grs. to 1 oz.), magnesium citrate and sodium citrate, 0.2 per cent. (1 c.c. of a 10 per cent. sol. to 10 cc. of blood, or 2 grams to 1000 c.c. of blood). Hirudin or extract of leech has been used by Satterlee and Hooker to rinse out specially devised apparatuses to prevent coagulation of blood, with good results.

The main advantage one may find in using medicated blood is that the recipient is not necessarily brought in proximity with the donor, and that the method is as simple as the injection of a solution of salvarsan. The objections, however, are well stated by the very men who advocate the addition of drugs for prevention of coagulation, namely that sodium citrate may cause transient polyuria; faint crenation of red blood cells, or rouleaux formation. Other objections are that, after storing blood five days in an ice box a mold has been found on it, so that it cannot be used; excessive doses cause cramps in guinea pigs. Furthermore we must add: exposure to air, dust, and germs while drawing it into the receptacle; chilling and reducing the temperature of the blood to that of the room temperature before it is injected into the recipient; blood which has been stored in an ice-box for further use must be warmed to that of the body temperature before being infused into the recipient; idiosyncrasy to the drug may prove harmful. The advocates of sodium citrate claim that hirudin is not easily obtained and is poisonous.

In a personal conservation Dr. Lewisohn has assured me that this method of adding 0.2 per cent. solution of sodium citrate to prevent coagulation of blood, is perfectly harmless to the system. Apparently, the return to agents which will prevent coagulation of blood is the confession of the want of a proper instrument that will enable one to do a blood transfusion with ease, accuracy, and rapidity.

Kimpton and Brown devised a paraffined tube composed of a glass cylinder with a specially curved cannula, and a method whereby suction or pressure may be applied for withdrawing or injecting blood. The vessels of both donor and recipient are dissected out, properly prepared, and incised. The top of the tube is inserted into the vessel of the donor, blood withdrawn, and immediately transferred into a similarly prepared vessel of the recipient.

The disadvantage of this method is that the glass tube requires special preparations. It has to be paraffined, baked in an autoclave, and is likely to be broken, so that several have to be kept in readiness to meet an emergency. Furthermore the blood is brought in contact with the foreign body which forms fibrin and plugs the needle and tube. A similar paraffined glass tube as the Kimpton Brown is that of Nelson M. Percy.

L. J. Unger has described a new method in the *Journal of the A. M. A.*, February 13, 1915. The instrument consists of a stop-cock which connects a syringe for blood to the donor, and a syringe for saline to the recipient; then by turning the cock the syringe with blood is immediately connected to the recipient and the syringe with saline to the donor. The cock has four outlets to which is attached rubber tubing of various sizes—the recipient and the donor's rubber tubes are paraffined. The instrument is supported by a stand to hold the cock stationary and to permit of its being adjusted to various heights in conformity with the levels of the veins. The stand is fixed to a table and by raising, lowering, or rotating the pedestal to which the instrument is attached connections to the cannulæ can be made.

We must be mindful that an instrument to be of universal value in rural districts as well as in the city, must have attachments which can be replaced with ease. The rubber tubes, two of which are paraffined, cannot be sterilized with safety. The paraffine dries, cracks, and chips off in time. The arrangement to fill the recipient with a quantity of saline solution has the same objection as the simple syringe cannula method.

When a quantity of saline must be added to the volume of blood given to the recipient, we either give an excessive amount of fluid and overtax the heart, or we give an insufficient quantity of blood in cases that require a maximum dose. Saline solution is not objectionable when given to a patient who needs it—when salt solution however can improve and cure the patient, no blood transfusion is indicated. On the other hand when pure undiluted blood is essential, the addition of salt solution is not desirable.

With the hope of finding an ideal method to perform blood transfusion with ease, accuracy, and safety, which would overcome all objections found in other methods, I have devised a valve made of steel, nickel, brass, silver, gold, or glass. It is in

reality a combination of a direct and indirect method for transfusion of blood. The valve consists of a central body with two arms going in opposite directions, and weighs two ounces.

The central part is cylindrical, 1½ inches long

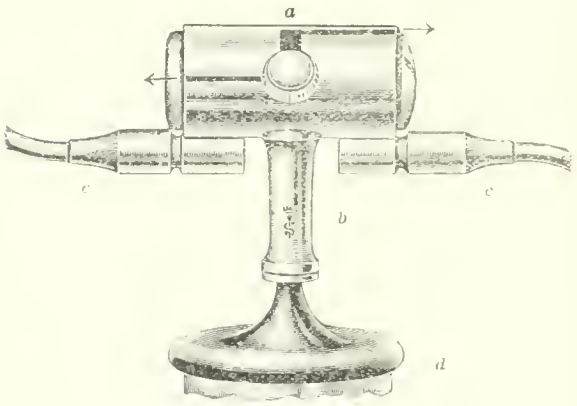

Fig. 1.—Transfusion apparatus. *a*, Cylinder; *b*, stem; *c*, *c*, arms; *d*, syringe.

and ½ inch in diameter. The middle of the upper surface of the valve has a thumb-screw arrangement which moves the interior metal filling of the valve back and forth within a play of ⅜ of an inch. The same back and forth movement can be arranged by a thumb-screw attached to the side of the valve instead of on the upper surface.

The interior metal filling of the valve has two grooves equal to the size of the lumen found in each arm. From the center of the under surface of the valve a cylindrical hollow stem passes down one inch long. The lumen of the stem is just large enough to receive the tip of a record syringe holding 10 c.c., 20 c.c., or 50 c.c. of fluid.

The two arms going in opposite directions are bent like an italic letter S, and begin from the under surface of the valve; one extends outward and downward until it reaches a point 1½ inches below and 2 inches away from the valve; the other extends outward and upward until it reaches a point 1½ inches above and 2 inches away from the valve. The total distance from the tips of the two arms is 5½ inches in length and 3 inches in width.

The two arms are hollow, of equal lumen, and are continuous with the grooves found in the interior metal filling of the valve. The tips of the two arms fit exactly to a cannula and needle used for transfusion or any needle which fits a record syringe. The two arms of the valve may be of rubber instead of metal to render it flexible.

By moving the thumb-screw arrangement of the top or side of the valve back and forth, the current of blood, or any fluid, can be directed into one arm or the other.

When one arm is open, the other arm is closed, and when the thumbscrew is placed in the middle of the ⅜ of an inch play the current is stopped from both arms. Either arm can be used for donor or recipient.

The distance in the length and width of the distal ends of the arms of the valve is approximately the distance between the median basilic or cephalic veins of two adults arms placed alongside each other.

Other vessels, such as the external jugular or saphenous, can be connected with the valve with the same ease as the vessels at the bend of the elbow.

The alternate action of the valve is of advantage to the recipient by preventing a continuous large volume of fluid from suddenly overtaxing the heart. During aspiration the heart has a chance gradually to distribute the added amount of blood without much exertion, thereby obviating cardiac dilatation.

There are a number of cannulæ on the market. Those which were devised by Lindeman consist of an inner fine hollow needle which passes through a middle cannula, this in turn telescopes with an outer cannula and the inner needle is 5 mm. longer than the middle cannula.

The cannula of Kaliski is an ordinary aspirating trochar and cannula; it pierces a bridge of heavy steel which raises the cannula hub sufficiently far from the skin to permit of the coupling of the syringe and its attachment without disturbing the position of the cannula in the vein.

The Unger cannula resembles that of the Kaliski, except that instead of an obturator, a hollow needle passes through the cannula.

To overcome some of the difficulties encountered in handling and steadying certain cannulas on the market, I have devised a special one. Two sets are necessary, one for the donor, and the other for the recipient. There are three parts to each set which consists of a cannula, a hollow needle, and an obturator. The needle and the obturator fit snugly and telescope in the cannula. The obturator and cannula are of equal length, 2⅝ of an inch, the hollow needle is ¼ to ½ of an inch longer than the cannula and is slightly grooved and beveled to a fine point. The proximal ends of the needle and obturator are capped with stationary thumb-screw caps. The cannula is capped with a receiver to fit the free ends of the arms of the valve or any record syringe. The caliber of the cannula is the same as the arms of the valve and the same as the tips of a record syringe.

One-half to three-quarters of an inch from the distal end, the cannula is encircled by a ring 1 mm. in thickness, and a second similar ring is placed 1 mm. away from it. The space between the encircling rings is just wide enough to receive a suture of silk, linen, or catgut which is temporarily placed by passing through the skin of the donor or donee to hold the cannula stationary in position, thereby preventing it from being shoved back and forth during aspiration and injecting of blood, or any fluid.

Operation.—The valve, cannulæ, needles, and obturators are sterilized by boiling, the same as other instruments before operation. One, two, or three record syringes of any kind which will fit the can-

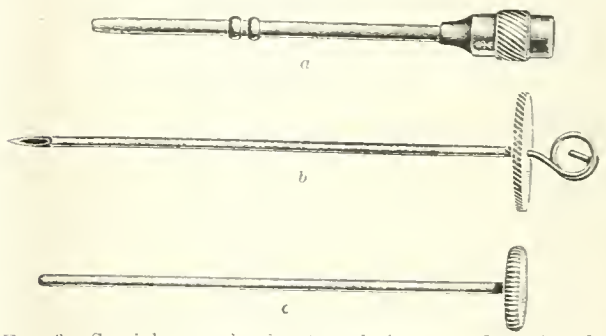

Fig. 2.—Special cannula for transfusion. *a*, Cannula; *b*, needle; *c*, obturator.

nula, usually 20 c.c., can be sterilized, either by boiling or by immersing it in 95 per cent. alcohol for a half hour and transferring it afterwards to a basin with warm normal salt solution.

The vessels usually selected are the median

basilic, or cephalic, the external jugular, or saphenous veins.

The area of operation is properly shaved, disinfected, and coated with tincture of iodine. A tourniquet consisting of a light weight rubber tube is applied and allowed to be on the donor during the entire time of the transfusion, but it may be temporarily loosened if the donor complains of numbness of the fingers and hand. The tourniquet must be applied to constrict the venous circulation but not the arterial. The patient's arm is prepared the same as donor's, tourniquet applied until cannula is inserted into the vein and then removed.

Donor and patient are placed in the recumbent posture on separate tables, at right-angles, head to head, with the donor's left arm against the recipient's right arm. Both arms are stretched to their full length resting on a small table, placed in the angle formed by the two long tables. The eyes are covered with a towel. Both long tables should be preferably of the adjustable kind for

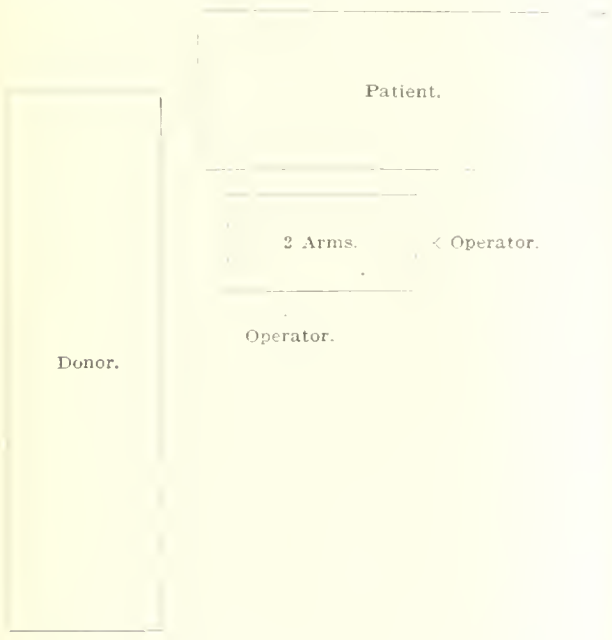

FIG. 3.—Arrangement of tables for donor and patient

Trendelenburg or Fowler's position, so as to permit combating either syncope or acute cardiac dilatation. The donor's table should be about a foot higher than that of the recipient; this helps to increase the flow of blood by gravity. One operator manages the donee, another operator manages the donor. The operators are standing or sitting near the small table.

The arm is gently massaged in the direction of the tourniquet, which helps to fill up the vein. Stretch the skin in the direction of the veins to be punctured by grasping the forearm with the palm of the left hand under the arm, using the thumb to steady and stretch the vein. With the right hand grasp the cannula telescoped by the needle, beveled point upward, between the index and middle finger, with thumb on the midle cap. Push the needle and cannula through the skin in toward the hand of the donor, and the shoulder of patient, and enter the lumen of the vein for about ¼ to ⅜ of an inch; then withdraw the needle a short distance to prevent puncturing the vessel wall, and continue to drive the cannula into the lumen of the vein until the ring on the cannula meets the skin and prevents it from going further.

Blood will be noticed coming alongside the needle; withdraw the needle, and if the cannula is not against the wall of the vein, blood will flow freely; then insert the obturator. Pass a suture through the skin and tie it between the two rings of the cannula to prevent it from slipping out. If blood does not flow freely through the cannula withdraw it slowly about ¼ to ½ inch, which often establishes the flow, proving that the tip was occluded by a valve or the wall of the vein. Do not aspirate or force saline through the cannula to ascertain if the cannula is in the lumen of the vein, it will infiltrate the tissues and distort the position of the vessel, so that another puncture of the vein will become necessary.

Donor and recipient can be operated upon in different rooms until this stage of the operation. The donor's table is now rolled into the recipient's room and the two tables are adjusted as described above.

Having placed the donor and recipient cannulæ in position remove the obturators and adjust the opposite ends of the valve to the receivers of the cannulæ, by a slight turn, to make them fit snugly.

Fill a 20 c.c. record syringe with warm saline solution and force the air from both arms of the valve before adjusting them to the cannulæ. Place the thumb-screw of the valve in the direction of the donor's arm. Commence to draw, very slowly, the piston from the record syringe and fill the syringe with blood, change the thumbscrew toward the recipient's arm, and empty the syringe with blood rapidly. Continue to alternate the directions of the thumbscrew, filling and emptying the syringe without removing the same from the valve, until the desired amount of blood has been transfused.

No saline solution is necessary for injection during the transfusion, one syringe is all that is required for the entire operation. It is, however, advisable to have two or three syringes in readiness in the event of unforeseen difficulties.

Difficulties may arise from slight tilting of the cannulæ of both donor and donee, which brings the tips of the cannulæ against the wall of the vessel. Proper steadying of the cannulæ by the assistants will prevent such occurrence.

When changing a syringe I have found it advisable to have it filled with saline solution and to allow some of the solution to pass into the donor and donee to ascertain whether or not the cannulæ are in the lumen of the vessels. By this method no blood is lost, and no air is present in the syringe.

I have by this method transfused 23 cases, 6 at the Jewish Hospital of Brooklyn, 2 at the St. Mark's Hospital, New York; 6 at the People's Hospital, New York; 1 at my office, 5 at the patient's home, and 1 each at Long Island College Hospital, St. John's Hospital, and the Swedish Hospital.

Before performing blood transfusion by any method, it is advisable, except in urgent cases, to make a Wassermann test of both donor and recipient, agglutination and hemolysis test; blood pressure, pulse rate, and cardiac examination. Blood examination as to number of red and white corpuscles, hemoglobin and coagulation test; complete urine examination. Operator and assistants should insure perfect asepsis as in the preparation for a major operation. Donors should not be stout, nor over 40 years of age, and free from disease.

When the veins are small, or in fatty individ-

CASES

Referred By		Patient's Name	Date	Age, Years	Donor	Quantity Transfused, C.C.	Place	Disease
Dr. J. B. Bogart	Case 1	Sussie N.	December 21, 1914	34	Husband	320	Jewish Hospital	Traumatic hemorrhage from right kidney.
Dr. G. S. Wolf	Case 2	Bessie K.	February 1, 1915	34	Alien	135	People's Hospital, New York	Ruptured, extrauterine pregnancy.
Dr. J. M. Polisar	Case 3	Jacob R.	February 3, 1915	29	Alien	300	People's Hospital, New York	Epistaxes several times a week for two years.
Dr. J. M. Polisar	Case 4	Jacob R.	February 26, 1915	29	Alien	320	At my office	Ditto.
Dr. J. B. Bogart	Case 5	Sussie N.	March 2, 1915	34	Husband	320	At her home	Anemia following traumatic hemorrhage.
Dr. Adolf Granet	Case 6	Hinde G.	March 17, 1915	60	Nephew	200	St. Mark's Hospital, New York	Septic cellulitis of arm (to overcome post oper. shock).
Dr. J. M. Polisar	Case 7	Nathan R.	March 20, 1915	25	Alien	100	People's Hospital, New York	Purpura hemorrhagica.
Dr. Adolf Granet	Case 8	Hinde G.	March 25, 1915	60	Alien	300	St. Mark's Hospital, New York	Chronic suppurative anemia.
Dr. S. Tirman	Case 9	Selina R.	April 2, 1915	50	Alien	135	Jewish Hospital, Brooklyn	Carcinoma of breast; anemia.
Dr. Leon Louria	Case 10	Bertha K.	April 3, 1915	60	Alien	100	Jewish Hospital, Brooklyn	Pernicious anemia.
Dr. Wm. K. Jacobs	Case 11	Julius S.	April 13, 1915	10	Father	225	Jewish Hospital, Brooklyn	Purpura hemorrhagica.
Dr. Sol. Rottenberg	Case 12	Annette K.	April 15, 1915	39	Alien	300	People's Hospital, New York	Post partum hemorrhage, t xemia.
Dr. John O. Polak	Case 13	Mrs. M.	April 23, 1915	30	Husband	400	Long Island College Hospital	Post abortum sepsis.
Dr. J. A. Kinnear	Case 14	Mrs. Antoinette S.	May 13, 1915	23	Father	300	At her home, Toronto, Canada	Post abortum sepsis.
Dr. M. N. Ratzan	Case 15	Joe G.	May 21, 1915	5	Father	140	At his house.	Pernicious anemia.
Dr. Chas. M. Bellows	Case 16	Mr. C.	May 16, 1915	76	Alien	400	At his house.	Anemia.
Dr. Chas. Fisher	Case 17	Dora L.	June 12, 1915	31	Sister-in-law	500	Swedish Hospital, Brooklyn	Post-operative shock.
Dr. Lewson	Case 18	Mrs. R.	June 14, 1915	40	Alien	200	At her home	Puerperal sepsis.
Dr. Leon Louria	Case 19	Mr. E.	June 29, 1915	29	Alien	500	Jewish Hospital, Brooklyn	Anemia.
Dr. A. Granet	Case 20	Max P.	July 4, 1915	9	Alien	100	People's Hospital, New York	Intestinal hemorrhage.
Dr. Morris Korshet	Case 21	Mrs. K.	July 8, 1915	52	Alien	100	People's Hospital, New York	Anemia.
r. Chas. Fisher	Case 22	Mrs. K.	July 9, 1915	46	Alien	200	St. John's Hospital, Brooklyn	Post-operative shock.
	Case 23	Simon K.	August 23, 1915	28	Alien	240	Jewish Hospital, Brooklyn	Pernicious anemia.

uals, it may be an advantage to cut down and isolate the vein for about a half to one inch, using novocaine or cocaine to infiltrate the tissues, or spraying ethyl chloride locally.

The valve will enable one to perform blood transfusion after a little practice, with ease, accuracy, and safety. There will be no loss of blood to any appreciable amount, nor will it be necessary to fill the patient with a volume of salt solution during the transfusion.

Nurses to wash syringes during the transfusion can be dispensed with and no dozens of syringes are necessary.

The formerly considered major operation for transfusion of blood will be, by the use of the valve, converted into an operation of minor character which can be carried out in the doctor's office or in the patient's home, without a nurse and with one assistant.

By the use of the valve there will be no need of medicating the blood in the hope of preventing coagulation.

In addition to the use of the valve for blood transfusion it could be used in place of the Potain syringe in paracentesis, etc. The cannula may be used for salvarsan injection, subdermic saline injection, etc.

In conclusion, I desire to state that I will cheerfully demonstrate and explain the instrument to surgeons desiring to use it in any case requiring blood transfusion. The instrument is manufactured by Kny-Scheerer Co., New York.

700 St. Marks Avenue.

PROPHYLAXIS IN DEMENTIA PRECOX AND OTHER PSYCHOSES.

By J. R. ERNST, M.D.,

WASHINGTON, D. C.

JUNIOR ASSISTANT PHYSICIAN GOVT. HOSPITAL FOR THE INSANE.

In the Medical Record of May 29, I endeavored to emphasize the fact that the early recognition of the precox type of individual and prophylactic measures were of paramount importance if we are to lessen the number of that class admitted to our institutions. It is well known that the majority of the hopelessly insane are of that type.

At this point the question arises, "Why do those, who contribute literature on mental and nervous diseases avoid or ignore the importance of prophylaxis in this condition?" Rational mental teaching has shown its value in hysteria and in many neurasthenic and psychasthenic states. Is there not a possible application of its principles to the very early stages of dementia precox, and, if so, what are the sources to which we must look for help?

I will not go farther in answering the first part of my question, other than to say that the teachings of Freud seem to have taken complete possession of these writers with the result that psychoanalysis is considered as offering the best hope for decreasing the number of this class of patients, and a possible prophylaxis in this condition is entirely lost sight of. While psychoanalysis is, no doubt, of great benefit, and has resulted in complete cures in selected cases of hysteria and neurasthenic conditions, its value in dementia precox is extremely doubtful. Its application to these cases in many instances has resulted in distinct harm to the patient, depending upon the fact that many of them have reached a fairly comfortable mental state, and when the psychoanalyst breaks up their adjustment, bringing ideas to the surface which are intensely disagreeable and loathsome to the patient, and suggesting strongly, almost to the point of hypnotism, that he has been guilty of various sexual perversions, many of them become suicidal or their condition is anything but benefited by the treatment.

The cases of undoubted dementia precox which have been cured or in any way benefited by the psychoanalytic method, are so few in number that the success of this method is far from encouraging, and writers on mental and nervous diseases would accomplish greater results if they turned their attention to prophylaxis.

The reason that psychoanalysis has met with such poor success in dementia precox, and has been fairly successful in hysteria and neurasthenic states, is due to the wide difference in the two conditions. This difference, while not readily apparent in the early stages, is nevertheless of great importance when the prognosis of the two conditions is considered. Dementia precox being a de-

teriorating psychosis going on to complete dementia, the psychoanalyst has a greatly impaired intellect with which to deal when the case comes under his care, due to impaired judgment or reasoning power. This makes it extremely difficult, if not impossible to gain the patient's cooperation.

On the other hand, hysteria and allied conditions may show hallucinations and delusions, but the progressive deterioration is not present, and the psychoanalyst meets with greater cooperation and a correspondingly better result is obtained.

The fact should not be lost sight of that dementia precox, as well as other abnormal mental conditions, is a disease and consequently has an etiology. Greater effort should be made to obtain information relative to the cause of this condition and thereby facilitate prophylaxis.

At present it is believed that the factors largely responsible in the causation of dementia precox may be grouped under three heads, viz., "Dementia precox in the immediate or remote ancestry, alcoholism, and abnormal personality."[1] Under the last division would be included "crankiness" and marital incompatibility. However, in addition to the above causes, recognized authorities on mental diseases[2] have called our attention to the great importance of the present school system as an etiological factor in exhausting the limited potential with which this type of individual is endowed.[3]

The first three etiological factors will be seen to deal with the remote and immediate ancestry, and the fourth with the early childhood and development of the individual.

It is obviously impossible in this paper to give more than a superficial discussion of these etiological factors and the prophylactic measures indicated. The removal of the first factor in the causation of this condition is the most difficult, and the result will depend largely upon the thoroughness of the campaign of education referred to later in this paper. "The right of a child to choose his parents" is a statement of greater importance than appears on the surface and applies directly to the subject under discussion.

The large amount of literature on eugenics that has flooded the professional and lay press during the last few years has already done great good by causing legislation along these lines, and, most important of all, it has been the means of directing the attention of the public to the fact that there are more important factors than sentiment to be considered when one is choosing a life partner.

The second factor, or alcoholism, is, without doubt, of great importance. Its common use as an aphrodisiac has, no doubt, been responsible for many a child being born with that "limited potential," which caused the "stranding on the rock of puberty."

It is difficult to obtain positive proof of its effect when used as an aphrodisiac, should conception occur, because of the inability to estimate the time of conception. It is well known that the offspring of a woman who has been addicted to alcoholics during pregnancy is very likely to be mentally defective.

When it is known that acute alcoholism causes a temporary loss of function of the higher conscious centers, as judgment, reasoning, moral sense, etc., and in the chronic alcoholic, causes a permanent loss of these higher intellectual functions, it is quite within the bounds of reason to believe that a man, or more especially a woman, addicted to alcoholics is quite likely to have one or more of his or her children turn out to be mentally defective. In many instances the alcoholism is but a symptom of neurasthenia, or of a dementia precox at a more advanced age, to which it in turn has contributed, and established a vicious circle which has left its impress in heredity. The removal of alcoholism as an etiological factor, like heredity, depends upon acquainting the public with its evil and far-reaching effect upon the human race. At least ignorance can no longer be the plea, and the medical profession will, in a measure, have discharged its duty to humanity.

The next etiological factor is the parent with an abnormal personality or pathological character, or the so-called "crank." As stated, we also have, under this heading marital incompatibility due to the inability of one or both parents to adapt themselves to commonsense relations.

Another subdivision of the pathological character is the class which may be termed "derelicts" themselves in all probability suffering in some slight degree from dementia precox coming on later in life. Many of these belong to the alcoholic class, and, after reaching manhood, they are unable to keep up the struggle and are forced to drop out and be content with small clerical positions.[4] On every hand we see this type, and they represent the semi-failures of life. This class is, no doubt, responsible for many cases of dementia precox in our institutions to-day. Marital incompatibility is a frequent cause and could be avoided if parents were informed of its importance.

The above etiological factors deal entirely with the parentage of the child, and successful prophylaxis will depend upon the extent the medical profession interests itself in educating the public. When one pauses to think that the individual having any knowledge of these things is the exception, he will not hesitate to join in the campaign of education and thereby hasten the day when the parents of these unfortunate patients cannot accuse us by saying, "I never knew" or "If I had only known."

The last etiological factor, or the present school system, is considered of great importance, and I believe that the best opportunity to accomplish immediate results in prophylaxis is in this field.

The root of prophylaxis of mental and nervous diseases lies in proper mental and moral hygiene for the young, and the physician as well as the educator and sociologist is properly looked to for the technical advice by the intelligent portion of the community, which needs to have its mind set at rest on various questions regarding their education.

The present public school system, with its unnecessarily crowded curriculum and the forced application of all types of intellects to the same subjects, without regard to their probable usefulness in the life of the individual or of the individual's adaptability, exercises a pernicious influence on the mental development of the child. Particularly is this true in the education of girls. They are compelled to apply themselves to the study of subjects to which they are temperamentally unfitted, thereby hastening their mental exhaustion, especially if their original amount of potential is less than normal, due to their being of a precox makeup.

An additional factor in the mental breakdown of the female patient is higher education. In institutions for mental and nervous diseases, where

statistics have been compiled, it has been found that the majority of women patients are those that have attempted difficult mental tasks and have pursued a course of study much better suited to the masculine mind. This common disastrous effect of strenuous mental application is due to the fact that woman, in the centuries past, has not had the mental training, due to the semi-slavery in which she has been held.

Another point to be considered by teachers and educators to-day is how to secure for the backward child adequate education in the public schools through separate courses of instruction suited to his capacity, in place of subjecting him to the vain struggle of keeping up with the brighter pupils, and also adopting a special curriculum for girls, suited to their future needs and their mental makeup.

The number of public measures in which we might profitably engage, although a formidable one, is only a part of what there is to be done, but persistent work directed to but one of them could hardly fail to be productive of much benefit to the community, and the physician, whether he be psychiatrist or family practitioner should, by means of the home, the press, and the school impart the results of his study to the community, not forgetting that the purely scientific side of the problem is useless, unless associated with practical effort and the production of a working plan. Among the thousands of patients who are to-day in institutions throughout the country there are many brilliant hopes buried, largely owing to a lack of knowledge of what some people need in the way of social and personal hygiene. It is the duty of the physician to familiarize himself with the etiological factors in these conditions and impart his information to the public, as in the prophylaxis of all diseases, our hope of eradication depends upon the education of the public.

Logically the lead in this movement should be taken by our national health organizations. At present we have the United States Public Health Service with a special department on mental and nervous diseases. This department is doing good work in the field of mental medicine. We also have the National Committee for Mental Hygiene which has been instrumental in the organization of many State societies for mental hygiene.

The medical colleges have, of recent years, become aware of the importance of mental disease and are devoting more time to its teaching. In keeping with the activities of the medical profession to-day, there is no doubt but that the greater effort of these organizations will be directed toward the prevention of mental disease rather than the treatment. With these factors at work as a nucleus the time is not far distant when the public will be as well informed regarding the etiological factors in the psychoses as they are at the present time, regarding the causation and prophylaxis of typhoid malaria, diphtheria, etc. Not until then can we hope for any marked diminution in the number of admissions to our institutions for the insane.

The only hope in sight for checking the increase of insanity lies in prophylaxis, and the neurologist and the family physician have exceptional opportunities for observation and study of its initial stages, at which time, alone, it is possible to avert or defer the attack. It is through the neurologist that the public should be informed of the indications of its approach and the means of warding off the attack, or at least protecting the individual and the community. It is for him to urge the adoption of public measures for the early treatment of the disease by the separate care of such patients among the poorer classes, either in wards of general hospitals or in special psychopathic hospitals. I will state here, that the old idea of considering an individual suffering from a psychosis as guilty of an offense against the community and committing him to an institution by criminal proceedings, thereby branding him for life, is a relic of barbarism and a disgrace to a civilized nation. Such an idea is but a relic of the days of grossest ignorance concerning mental disease, the days before Pinel started the movement which awakened the profession and the world to the fact that an individual suffering from mental disease is not possessed of devils or guilty of any criminal act, but is sick, mentally sick in the same sense as one becomes ill from any other disease.

Thanks to a few enlightened minds who have seen the injustice of this method, several state legislatures have recently passed voluntary commitment acts and thereby set an example which other states should lose no time in following.

Another promising field for public preventive work lies in the temporary supervision, protection, and relief, by means of charitable aftercare associations of poor patients, who are discharged from hospitals for the insane as recovered or convalescent. In this way alone can we hope to prevent relapse or prolong the intervals of sanity between attacks, that are inevitable. This plan is being followed out by New York with gratifying success and should be the method adopted by all of our institutions.

Eugenics—the practical application of facts learned in the study of heredity—is one of the most recent undertakings for race betterment, dating back little more than twelve years, while that branch of it relating to heredity in mental defects and diseases was taken up scarcely more than five years ago, research work therein being confined to this country and Germany.

From the results already obtained we can see how important to our descendants is a complete knowledge of the transmission of insanity and mental defect by heredity. For many years the popular mind has associated insanity with heredity. This belief has been confirmed by modern investigation so far, at least, as to assure us that heredity is by far the most important single factor in the causation of certain forms of mental disease.

To ancestors afflicted with feeblemindedness, with dementia precox, and other mental disorders, numerous mentally defective or mentally diseased descendants have been traced in many of the families that have been investigated, while in a few of the cases examined, where one party to the marriage was normal (and presumably of normal ancestry) the other being insane, some normal children resulted.

The result of investigations of heredity in mental diseases and defects down to the present time entirely justifies the statement that it is highly undesirable that the feebleminded, epileptics, and those with certain types of insanity should have children.

Looking at prophylaxis from the standpoint of a citizen of the United States, who does not wish to see his country made the dumping ground for

all sorts of mental defectives, who propagate other defectives, and in a short time become a burden to the state and nation, I cannot emphasize too forcibly the great importance of recognizing the defective and future precox before he is admitted to this country.

In closing my article, I will here give a few very important suggestions published in a recent report on the Alien Insane in the Civil Hospitals of New York State.[5] It is recommended:

(A) That, as an aid to existing methods, there should be stationed at the ports of embarkation United States medical officers, who should take part in the examination of the intending immigrant.

(B) That there should be stationed upon each ship bearing immigrants to this country United States officials, either physicians or nurses, or both, who should observe the aliens from time to time and report to the immigration officials, upon arrival, those apparently suffering from psychoses or mental defects.

(C) That a larger number of medical officers should be detailed to Ellis Island and other large ports, and that these physicians should be men trained in the detection of mental diseases and and defects.

(D) That there be provided large detention hospitals in which suspected cases could be isolated for a longer or shorter period until proper investigation could be made as to their mental condition.

(E) That the time during which deportation can be effected under Federal warrant be lengthened to five years or longer.

(F) That the testimony of competent alienists as to mental condition be taken as sufficient authority for the issuance of Federal warrants of deportation, if other conditions admit.

(G) That the law, instead of providing that the authorities show that the causes of the alien's psychosis existed prior to his landing, should provide that the alien should show that the causes of his psychosis arose subsequent to his landing, thus putting the burden of proof upon the alien rather than upon the state.

(H) That the steamship companies which bring immigrants to this country be made responsible for the mental condition of the immigrants, as well as for the physical condition. In other words, the steamship companies shall make careful investigation into the family history and general surroundings of the proposed immigrants at their homes in order to determine that there is no hereditary taint.

(I) There is need for the employment at the ports of entry of more trained alienists. These officers have to devote much of their time to examinations for physical diseases and defects. That the force of alienists has been insufficient is shown by the increase in the number rejected on the mental examination whenever in the past additional alienists have been assigned to duty at Ellis Island.

(J) As far as possible, physicians skilled in the detection of mental diseases and defects should be selected from the candidates for admission to the United States Public Health Service.

(K) Physicians in this service should be detailed for training at hospitals for the insane in order to insure a greater number of alienists. This was done at one time, but was discontinued some six years ago.

(L) The three foregoing recommendations can be put into effect without legislation except the necessary appropriations for pay and allowance for the additional officers needed. Unless these things are done much of the legislation recommended for the detection of the insane in the mental defectives at the ports of entry will be ineffective.

(M) Employment and careful training of a sufficient number of interpreters for this part of the medical examination is needed. A difference of opinion as to which department of the Federal government should employ such interpreters has prevented their appointment. This is a trivial matter, compared with the great importance to the states which bear the burden of the alien insane, of providing such urgently needed assistance.

In conclusion, I will say that I am well aware that this article adds nothing to what has already been written on the subject, nor was it written with that end in view, but rather with the sincere hope that it might be the means of arousing the medical profession to a full realization that present methods of attacking the psychoses have not achieved results and the admissions to our institutions are on the increase.

If this is thoroughly understood and appreciated, all will agree that it is imperative that increased efforts along the line of prophylaxis are absolutely necessary if we are to achieve results of any consequence in our attack upon the psychoses.

To us, who associate daily with these unfortunates, and witness their pitiful state, realizing the possibilities wasted, the blasted hopes and ruined careers of those who might now be leading happy and useful lives, to us is brought most forcibly the necessity of doing something to diminish the steady stream of admissions of this unfortunate class.

No physician can feel that he has discharged his full duty to humanity until this result is achieved.

PNEUMOCOCCIC INFECTION OF THE THROAT.

By WILLIAM C. SANDY, M.D.,
COLUMBIA, S. C.,
MEDICAL DIRECTOR, SOUTH CAROLINA STATE HOSPITAL FOR THE INSANE; FORMERLY ASSISTANT PHYSICIAN, KINGS PARK STATE HOSPITAL,
AND
CHARLES G. McGAFFIN, M.D.,
KINGS PARK, N. Y.
ASSISTANT PHYSICIAN AND PATHOLOGIST, KINGS PARK STATE HOSPITAL.

THE pneumococcus has long been recognized primarily as the most frequent infectious agent in pneumonia of the lobar type. While other organisms have been isolated, occasionally in pure culture and frequently as mixed infections, the *Diplococcus lanceolatus* of Fraenkel and Weichselbaum, described in 1886, is considered the specific etiological factor in 90 per cent. of cases[1]. There are several facts, however, which complicate the etiological significance of the pneumococcus and make it necessary to presuppose what is generally accepted, accessory causal factors, such as diminished

resistance and local changes in the respiratory system favoring infection. In the first place, it is a well known fact that the pneumococcus appears in the sputum of healthy normal individuals and is not to be considered an abnormal inhabitant of the mouth and throat[3]. It may very likely be that the pneumococcus, found in the mouth and throat cavities of apparently healthy persons, belongs to one of the less virulent strains or races of pneumococci, as it has been shown by investigation that there are a number of different strains or races, varying in degree as to the severity of toxic effects[2, 3].

Again, so-called pneomococcus carriers appear from time to time in the case of persons who may have suffered from pneumonia some months before and in whose mouth or throat cavities the presence of the pneumococcus may be discovered only by accident[2, 3]. Such an instance was recently observed by a colleague, Dr. Walter H. Sanford:

A robust individual who had had pneumonia a year previously and who consulted the physician for the relief of a cough. The latter almost disappeared under treatment, but two weeks later, on a second examination, the patient was again coughing more or less constantly and expectorating a pinkish tenacious mucous which seemed to come from the trachea and larger bronchi. The sputum when stained seemed to be an almost pure culture of pneumococci. He had no fever, felt quite well and seemed in good physical condition aside from the cough. Examination of the chest was practically negative, there being heard only a few rales beneath the sternum. The cough yielded readily to treatment, and a second smear showed only isolated pneumococci. There was evidently a slight degree of bronchitis, but the patient did not appear to be ill and only consulted a physician largely because of the peculiar expectoration.

Although pneumonia may be regarded as the most usual result of a pneumococcic infection, yet other portions of the body are attacked with varying frequency. As complications of a pneumonia, or more rarely as apparently primary conditions, conjunctivitis, pleurisy, empyema, pericarditis, endocarditis, meningitis, otitis media, osteomyelitis, arthritis, and peritonitis[1], may be mentioned. Cases of ulcerative endocarditis without pulmonary lesions have been not infrequently observed[1]. Pneumococcic septicemia, about which there has been some difference of opinion as to frequency of occurrence, certainly may be proven in severe pneumococcic infections[4, 8]. Recently a case of extensive destruction of the vulva and adjacent tissues[5], probably due to pneumococcic infection, was reported.

Inflammations of the nasopharynx, due to the pneumococcus are, according to the literature, rather rare but important, especially from the standpoint of prognosis. Walb[4] has called attention to numbers of cases of a febrile affection which have occurred at Bonn during the last few years and which seemed to be typically influenza. In none of the cases, however, was the influenza bacillus found but, on the contrary, the pneumococcus proved to be responsible. The lesions were in the nasopharynx and at times involved the ear and the sinuses of the nose.

A few instances of a septic condition of the throat of pneumococcic origin are on record, some of which have shown a peculiarly fatal course. Tweedie[6] reported "three fatal cases of pneumococcal infection of the throat." Two of the cases, called by the author "asthenic" were rather chronic conditions, lasting several months, while the third, called "sthenic" ran a comparatively rapid course, lasting about ten days. All three showed extreme resistance to all forms of treatment and no cause, apart from the presence of the pneumococcus in the throat, could be ascertained. The organism appeared in large numbers in pure culture on the swabs or sputa. The first two cases showed practically nothing abnormal in the nose, ears or pharynx. There was an inflammation of the cartilages of the larynx, accompanied by a purulent discharge, which abounded with pneumococci. A phlegmonous condition of the neck added to the marked dysphagia. The third case showed a generalized subacute nasopharyngitis and a severe cellulitis of both submaxillary and submental regions. In none of the cases did incisions in the neck disclose pus. A postmortem examination in the third showed a small necrotic area about a half inch in diameter in the depths of the right submaxillary lymph glands. Blood and cerebrospinal fluid taken after death proved sterile.

Theisen's[7] cases, which recovered, were accompanied by severe edema of the pharynx, including tonsillar region, soft palate, and uvula, in several the epiglottis being involved. There was naturally severe dyspnea. Incisions failed to discover pus. Active treatment with hexamethylenamine internally in large doses and cold antiseptic sprays was used. While there was a mixed infection in several of these cases, the pneumococcus predominated in all.

Two cases, which came to the writers' attention recently and which provided the text for the present paper, seem to illustrate a peculiarly fatal type of pnemoococcic infection of the throat. The first was a private case of Dr. William B. Gibson, of Huntington, L. I., who kindly furnished his notes on the same.

Case I.—L. B. Age 43, an Italian contractor, of temperate habits and remarkably good physique, was taken ill on April 8, complaining of the usual symptoms of grippe, with slight sore throat. His family history is negative, mother being still alive, father dying at the age of 56 of some cardiac lesion. On April 9, he had an intense sore throat, temperature being 104°. There was no peritonsillar abscess, but the whole phraynx was deeply injected. It was with difficulty that the mouth could be opened. On the morning of the tenth, the physician saw him very early. He complained of difficulty of breathing. There appeared to be no obstruction in the throat. At the base of the right lung, a few crepitant rales were heard, apparently the first stage of a lobar pneumonia. Numerous pneumococci were found in a smear of the sputum. An injection of antipneumococci serum was made. At noon, when it was intended to give another injection, he was very restless and distressed, face suffused and temperature 105°. At 3:00 P.M. he continued restless and delirious, failing rapidly and dying at 4:00 P.M. Pulse was very full and tense up to noon of the day of death. No autopsy.

Case II.—J. W. White; age 79 at death; single; nativity Germany; a domestic servant. There is very little information available about the patient's early life. She had been an inmate of a State Hospital for the Insane for about thirty-four years, being at the Long Island State Hospital some twenty years, then discharged, working four years as a domestic servant, and on May 15, 1901, being recommitted, this time to the Kings Park State Hospital, Kings Park, N. Y.

She was always quiet, rather simple and childish in manner, for many years giving one the impression of marked constitutional inferiority or imbecility. However, from her past history of hallucinations of sight and hearing, some ideas of persecution, a general attitude of indifference and apathy, with disorientation, memory defects and the like, she was classed with the dementia praecox group. For a number of years, she had been very obese, weighing at the time of death 209 pounds, her height being 4 feet 11 inches. Aside from this excess of adipose tissue, there had been nothing to

call attention to her physical condition. She continued to be up and about the ward, helping with the mending, until about April 9, 1915. At that time she had a chill, complained of sore throat, and was put to bed. As there had been a number of cases of follicular tonsillitis on the ward, this was suspected to be her ailment. On examination, a peculiar intensely congested and edematous appearance of the mucous membrane, involving the uvula, anterior pillars, tonsils and a portion of the roof of the mouth, the border of which seemed sharply defined, differentiated it from follicular tonsillitis. Subjectively, the patient complained of considerable dysphagia and a choking sensation, although she seemed able to swallow fluids quite easily and her respirations were normal. The constitutional symptoms were not marked, the temperature being only 101° at the beginning, which was the highest fever, respirations 26, pulse 110. She had some laryngitis, with hoarseness of the voice.

She was given a gargle of peroxide of hydrogen one part, water four parts, and internally sodium salicylate, and calomel one grain in divided doses, followed by magnesium sulphate. For the nine days following she never appeared very ill. She remained in bed most of the time, but when necessary, walked to the water section. She developed a small area of cutaneous redness, swelling and induration in the submental region, which, however, was slight, did not spread, had not the characteristics of erysipelas and, after treatment by ichthyol ointment, disappeared in a couple of days. The congestion of the pharynx continued as described, but did not extend. Neither ulceration nor membrane developed. Treatment seemed to have little or no effect, yet the whole condition, so far as subjective complaints and constitutional symptoms were concerned, seemed rather trivial. After the first day, her temperature varied from 99° to 100°, there being a slight rise in the evening, the pulse and respiration bearing the usual relation to the fever. At no time were there symptoms referable to the chest, there being no cough, dyspnea or pain during respiration, and physical examination of chest, although not satisfactory on account of extreme obesity, seemed to be negative. Following gargling of the throat on April 17, she expectorated, without coughing, considerable thick mucoid material. A smear stained by Gram method showed pneumococci. She had taken milk freely, also fruit juices, until April 18, when she showed some anorexia. She took sufficient nourishment, however, after a little urging and seemed as well as usual. On the 19th, she went to the water section as usual in the morning and assisted in her treatment, co-operating in gargling her throat. At 9:30 A.M., however, she had a sudden violent chill and severe dyspnea, dying before a physician could be summoned.

Necropsy performed eight hours postmortem: Body is that of a very obese white female, 154 cm. in length and weighing 200 pounds. Pupils are equal and regular in outline; no malformation, deformities or evidences of injury.

Ventral Section: Abdomen: Full, rounded and pendulous; panniculus 5-8 cm. in thickness; abdominal muscles thin, but of good color. The omentum and mesentery are loaded with yellow fat; there are no adhesions throughout the abdominal cavity and no fluid exudate; diaphragm normal. The appendix is free throughout and measured 8 cm.; meso-appendix well formed. Thorax: Chest inclined to be barrel-shaped; mammæ pendulous; subcutaneous fat thick; pectoral muscles normal. The lungs are voluminous, and with the heart, completely fill the cavity. They are free from adhesions and there is no fluid in the thoracic cavity.

Circulatory System: Pericardium: The sac is surrounded by much fat; internally there are no adhesions or excess of fluid. Heart: 395 gms.; much fat on the surface; myocardium feels soft and flabby and is friable; cavities are dilated and swollen with fluid blood; valves show nothing of note. Vessels: Coronaries are thickened, but show no calcification; aorta shows numerous small calcified areas; no varicosities. Lymphatics: Lymph nodes show no hyperplasia; thoracic duct normal.

Respiratory System: Trachea and bronchi appear congested, and there is much mucoid exudate. Right Lung: 370 gms.; pleural surface smooth. There is a small amount of congestion and edema present; no signs of consolidation and substance crepitates throughout. Left Lung: 375 gms.; similar in all respects to the right.

Alimentary System: Esophagus: Normal. Stomach: Somewhat distended with gas and contained a small amount of light colored semifluid material; mucous membrane presents no congestion or hemorrhagic areas. Intestines: Normal. Liver: 2090 gms.; surface is smooth; no scars or adhesions; capsule not thickened; on section the tissue is soft and friable; light in color and has a greasy feel. Gall Bladder: Contains a small amount of tary bile and six small facetted stones. Pancreas: 70 gms.; light colored and soft. On section the tissue is almost entirely replaced by fat.

Genitourinary System: Right Kidney: 145 gms.; capsule not adherent or thickened; pelvis large and filled with fat; cortex thin; pyramids well made out. Left Kidney: 168 gms.; similar to the right. Ureters: Normal. Bladder: Walls are thickened; lining membrane covered with mucous. Uterus and Appendages: Further than atrophy, nothing of note.

Ductless Glands: Spleen: 260 gms.; capsule is smooth and shows slight thickening in small scattered areas; on section pulp is soft. Adrenals: Present central softening. Thyroid: Not examined. Pituitary: Normal in the gross.

Head: Scalp: Covered with a good amount of grey hair; normal thickness and stripped easily from the bone. Calvarium: Normal. Dura Mater: Thickened and very adherent to bone and slightly so to pia along median fissure. Pia Mater: Not thickened and no exudate. Brain: 1290 gms. before dissection; 1280 gms. after dissection. There is no apparent atrophy in the gross; surface pattern is regular; no areas of softening or gliosis; ventricles smooth; small amount of fluid; choroid plexuses normal; on section nothing of note. Basal vessels are sclerotic, but not calcified. Spinal Cord: Not removed, but upper portion appears normal.

Bacteriological Examination: Smears of mucus in both bronchi, stained by Gram's method and pyronin, showed numberless pneumococci. Smears from cut section of the lungs disclosed no organisms.

Anatomical Diagnosis: Obesity. Chronic external adhesive pachymeningitis. Slight chronic internal adhesive pachymeningitis. Cerebral arteriosclerosis. Slight pulmonary congestion and edema. Slight acute bronchitis. Cardiac dilation. Fatty degeneration of heart muscle. General arteriosclerosis. Fatty infiltration of liver. Cholelithiasis. Slight acute splenitis. Fat renlacement in pancreas. Central softening of adrenals.

In conclusion, it would seem that these two cases are examples of an acute pneumococcic infection, in which the toxic effects were far more severe than the symptoms or local physical signs would lead one to infer. It must be admitted, however, that case number two presents other features postmortem which were undoubtedly important as accessory causes, but the general symptoms and physical signs would seem to justify the opinion that the acute pneumococcic infection acted as the primary and important cause of death.

Syphilis and the Abderhalden Reaction.—G. Sangiorgi and M. Trossarello find in contradiction to the results obtained by certain American observers that the Abderhalden reaction has no value in the diagnosis of syphilis. This is the case whether the antigen employed is obtained from the human being or whether it is derived from the rabbit.—*Pathologica.*

THE RELATION OF LANDRY'S PARALYSIS TO POLIOMYELITIS.*

By M. NEUSTAEDTER, M.D., Ph.D.,

NEW YORK.

LECTURER IN NERVOUS DISEASES AT THE N. Y. UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE.

In 1859 Landry described the following characteristic symptom complex: Individuals who up to the time of their illness have been in perfect health develop a flaccid paralysis in the lower extremities, preceded by a general malaise and paresthesias in the affected parts. Within a few days the muscles of the trunk and then those of the upper extremities become involved in the same manner. And finally the muscles of deglutition, articulation, and respiration become paralyzed, and the patient dies of respiratory failure within a few days or weeks. Exceptionally some cases present a mild degree of these phenomena and survive without leaving any residual paralysis. In these cases the muscles last affected are the ones first to recover their function. He points out that there is no atrophy of the muscles and no electrical changes in them, and that he found no pathological changes upon autopsy.

A great many cases, however, have been reported that vary from the first description. Muscle atrophy with electrical changes is frequently observed, sensory disturbances are not uncommon, involvement of sphincters is at times reported, and a unilateral or bilateral facial palsy of Bell's type has been described.

Owing to the more advanced methods of examination the conception of the etiology and pathology of the disease has undergone marked changes. Although Landry was inclined to ascribe the affection to a toxic process, Westphal first demonstrated this to be a fact. The fact that in the majority of cases there are an enlarged spleen, swelling of the lymph glands, hemorrhagic foci in the lungs and intestines, and a nephritis points to a toxic or infectious process. Chantemesse and Ramon observed a large number of cases of paralysis, clinically not dissimilar to Landry's, in an epidemic form at an institution for the insane, suggesting a possible infection. Baumgarten found in one case *Bacillus anthracis* in the blood, and Curschmann cites a case in which typhoid bacilli were found in the spinal cord, of which pure cultures could be grown. Centanni found in a case of interstitial neuritis bacilli in the endoneural lymph spaces. Eisenlohr reports a case of Landry's paralysis due to a mixed infection. He found *Staphylococcus pyogenes* and *Staphylococcus cereus albus* in the spleen and sciatic nerve. In another case he found several types of bacilli. Remmlinger found *Streptococcus longus* and Marinesco diplococci which were partially enclosed in leucocytes. In a case of Marie and Marinesco a bacillus similar to that of anthrax was found in the blood. A virulent pneumococcus was shown to be present in the cases of Roger and Jesué, and of Courment and Bonne. Macnamara and Bernstein grew a tetracoccus from the blood and cerebrospinal fluid of their case, and Sheppard-Hall a streptococcus from his case. F. Buzzard isolated a coccus from the dura which produced a flaccid paralysis in animals. Wochenius found *Staphylococcus pyogenes albus* in the spleen and peripheral nerves.

In recent years, on the other hand, cases of Landry's paralysis have been reported in which no germs were found. Such cases are reported by Seifert, Schultz, Thomas, Kapper, Workman, Hunter, Burghart, Mosny and Moutier, Pfeiffer, and E. D. Fisher.

No less uniform is the pathology of this disease. Not only in former days but also in recent years the microscopical findings were negative in some cases as reported by Ormerod and Prince, Seifert, Kapper, Hun, Girandeau-Levy and others. Goebel and Burghardt report cases with very slight changes. In some cases disseminated foci of an inflammatory character were found in the bulb only; in others again exudates with capillary hemorrhages in the spinal cord only. Wappenschmidt has placed particular weight upon hyaline thrombi in his case as tending to prove the theory of Recklinghausen and Klebs that they are due to the action of bacterial toxins. In a few instances a marked swelling of the axis cylinders in the anterior pyramids was noticed. Widal and Le Sourd mention a neuritis of the roots as the only change.

Since the peripheral nerves began to engage the attention of investigators of these cases, some authors have been able to demonstrate extensive neuritic changes as the basis of this disease. Dejerine and Goetz, Nauwerck, Barth, Ross, Putnam, Klumpke, Boinet, Rolly, Pelnar, and E. D. Fisher report such types.

In recent years the majority of cases reported have been characterized by myelitic or rather poliomyelitic changes in the cord and midbrain, namely, by a perivascular and pericellular infiltration of various types of cells, hemorrhages, thrombosis, and softening. In no few instances, however, a combination of the neuritic and poliomyelitic changes were reported, as in the cases of Krewer, Mills-Spiller, Guizetti, and Knapp and Thomas. In these cases, Krewer argues, the inflammatory process of the peripheral nerves is extended to the cord and bulb, and thus gives rise to the symptom complex of Landry.

With such a varying etiology and pathology of a disease a uniform nosological character can certainly not be thought of. The disease may follow diphtheria, pneumonia, typhoid, variola, anthrax, influenza, and manifest itself as a puerperal polyneuritis. Some even report cases that developed after cystitis with uremia, others claim alcohol and syphilis as etiological factors, and a few have observed the affection to follow traumata complicated by septic cellulitis.

No less important is the fact that we do not know the point of entrance of the germ, nor have we any proof of its manner of dissemination. Furthermore, there is no evidence to show whether the toxin alone or the virus, or both, are responsible for the changes in the tissues.

Poliomyelitis.—The symptomatology of this affection is by no means uniform. In all cases, it is true, fever is the first symptom, but only one-third are accompanied by gastrointestinal disturbances. Headache and pain along the spinal column are as a rule a constant accompaniment. Meningeal symptoms are present in a large majority of cases. Stupor is rare; the intellect is clear.

The focal symptoms, as we all know, are not uniform. We have come to recognize the spinal, cerebral, bulbar, pontine, cerebellar, and mixed types. In the spinal type we have, of course, the flaccid paralysis of one or more extremities, with marked atrophy and reaction of degenera-

*Read before the New York Neurological Society, June 1, 1915.

tion, according to which segments may be involved. It is rarely of an ascending character. In cases that end fatally we hace a simultaneous involvement of the bulb and spinal cord. The cerebral cases, it is quite obvious, result in a spastic hemiplegia, with or without epileptiform convulsions. The purely bulbar or pontine types yield cranial nerve involvement. A peripheral facial paralysis is the most common result. Ataxia and tremors, with nystagmus, we find in the cerebellar cases. In the mixed types the symptom complexes vary with the site of the lesions. Some authors described a polyneuritic type, but this is rare, and was observed only in large epidemics. And finally a large percentage of so-called abortive types are recorded.

That its etiology is uniform no one will gainsay. The disease is preeminently an infantile one; it occurs in epidemic form; and shows very definite seasonal variations in its incidence. We all agree that it is both infectious and contagious. Flexner and Noguchi have definitely proven that there is a distinct coccus that produces the disease. Many important data about the character of the virus are available. I have established the fact that the nasopharynx is the point of entrance into the system.

The pathological changes of poliomyelitis are uniform in every case. It matters not what part of the central nervous system is affected. And that is true of clinical and experimental cases as well. Macroscopically, there is a pronounced hyperemia of the cord and meninges. The vessels of the brain are congested, and there is always a fair amount of edema of the brain and cord. There is little, if any, increase of the cerebrospinal fluid. On section the brain and cord have a moist, translucent, edematous appearance, and the gray matter of the cord is often swollen so that it projects above the level of the white matter. Frequently punctate hemorrhages can be discerned with the naked eye. The virus, as has been established, is propagated by the lymphatic system, and we have, therefore, foci of congestion and edema in various glands.

Histologically the disease is characterized by a perivascular, interstitial, and pericellular infiltration of round mononuclear, polymorphonuclear and endothelial cells. The ganglion cells involved are those of the anterior horns, Clarke's columns, spinal ganglia, nuclei of the cranial nerves, basal ganglia, and the cortex. Chronologically the perivascular lymph spaces of the pial vessels in the anterior longitudinal fissure of the cord and the pericellular lymph spaces of the spinal ganglia are the first ones to be involved. This has been experimentally demonstrated as early as on the third day after infection. This infiltration follows along the sheaths of the central vessels of the cord into the anterior horns. The vessels of the white matter do not escape the invasion. Furthermore, there may be a diffuse or simply focal infiltration. The capillaries are engorged. Hemorrhages are always present.

Since we have a definite species of bacterium to deal with in this affection, it is imperative that we show whether the germ or its toxin is at work, or both. It has been established by experiments and clinical observation that, whatever exotoxin there may be, it is a negligible quantity and of no great toxicity. Nor is the endotoxin very toxic. I have succeeded in liberating the endotoxin, and found that the product of a suspension of a virulent virus, of which 0.1 c.c. did bring a monkey down in six days, would kill a rabbit of 900 gm. only when injected with 15 c.c. Clinically we have cerebral symptoms of a mild type, which are due to a hyperemia, and not excessive toxemia.

And lastly, the cytological findings in the blood and spinal fluid of cases of poliomyelitis are so typical that for a time those were thought to be the criterion of the affection. The blood presents quite early in the disease a leucocytosis, with a predominance of mononuclears. The spinal fluid in the early stage is clear, and contains 85 per cent. or more lymphocytes. The cell count may range anywhere from 30 to 900 cells per cubic millimeter; its globulin content is increased, and its reducing property of Fehling's solution is intense. I, therefore, conclude that:

1. Landry's paralysis is a clinical entity with varying pathological changes. These may be primarily in the peripheral nerves, and confined to them, or they may be myelitic only, and again neurocellular.

2. Poliomyelitis is a pathological entity with varying symptom complexes. There may be flaccid paralyses, with muscle atrophy, or spastic paralysis, or cranial nerve involvement, also ataxias and tremors, or mixed types.

1215 Park Avenue.

MEDICAL COLLEGES RESPONSIBLE FOR MANY SPIRIT AND DRUG ADDICTS.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

It has been observed that some professors of therapeutics who enthusiastically praise opium, its alkaloids, cocaine, and coal tar derivatives for their good effects, are literally training a certain number of students to become addicts in the future. Statistical studies of inebriates and drug takers, particularly among the medical profession, indicate that a certain number began to drink and take drugs during the time of medical training. Years ago this was more common than at present. The

old-time teachers used to urge students to test personally and otherwise many of the drugs, so as to have some actual data concerning their effects. In later times the professors often refer to their own experience in hospitals, of the effects of certain drugs, to show that the statements in the textbooks are reliable. A medical teacher, now dead, for years gave lectures on opium and its alkaloids, cocaine and its possibilities. He described personal experiments with them on himself and others, and their effects, in such a graphic, entertaining way, that many of the students became fascinated. Years afterwards he resigned and died later, when it was ascertained that he was a drug addict. A study was made of the students who graduated under his teaching for a period of ten years, and it was found that a number of them every year became literally spirit and drug addicts. Another teacher of considerable eminence extolled these drugs and in a textbook which he wrote there was little said of the danger from their use, but very graphic descriptions were given of the good effects following their narcotic action. It was noted that a number of the graduates of this college became drug takers, and the inference was clear that his vivid teachings and praise of the action of the drug was responsible for this. This undoubtedly exists to-day, although probably very much less than formerly. The modern textbooks on materia medica and therapeutics give evidence of this in the detailed descriptions of the action of narcotics, with very brief reference to their possible dangers.

Not long ago alcohol was considered a stimulant of pronounced value and its use was urged in almost every condition of disease with little or no reference to any dangers from this source. Now alcohol is seldom mentioned as a drug and little or no reference is made to the dangers from its excessive use. In four of the largest and most prominent medical schools in this country the teachers of therapeutics and practice say very little about its value except in certain diseases, and nothing of its dangers. Opium and its alkaloids receive a much more detailed study, some with great exactness, but there is the same hesitancy and conservatism about the possibility of being injured by it. It is safe to assume that these colleges are teaching substantially what is taught in other colleges and implying by their teachings that excessive use of any of them is largely a matter of moral lapses which it is not the province of science to discuss.

A recent example is probably not unsual and in all probability it explains the early death of a number of good men. A physician and teacher of unusual eminence became an invalid at 45 and confessed to have taken spirits and opium at nights for many years and yet no one suspected his addiction. It was found that he began using drugs on the advice of a teacher to overcome disordered conditions and derangements of digestion and had continued it with more or less secrecy up to the time of his final collapse. The use of spirits and drugs among teachers is not uncommon. At college banquets this is confirmed by the habits of the professors who drink or abstain without evident care for their example. In some colleges there are students' banquets in which the professors join, there is little change. All drink as in olden times. In others the opposite prevails. Professors who write textbooks for the students indicate very clearly their own private convictions concerning spirits and drugs, not so much by what they say as by what they leave unsaid.

In 1913 a canvass was made of the habits of teachers in over forty different colleges in the large cities where several thousand students were studying. In every one of these colleges there were so-called moderate drinking professors. In only a few were there distinct total abstainers who asserted their views on this subject with positiveness. The other were noncommittal, and while apparently temperate men in the sense of abstaining from spirits and drugs, treated the whole subject as of little or no importance. The former ridicule and sneers which greeted total abstainers and persons who refused to take any spirits have passed away.

Forty years ago the late Dr. N. S. Davis always concluded his course of lectures on practice at the Rush Medical College with a special lecture on the dangers of alcohol and the necessity for its cautious use. These lectures were considered by many as a sort of a joke and tolerated as the fad of a good man. Years afterwards at his death there were many testimonials from his students all over the country that these were the most valuable talks and had helped them more than anything else he had said. From 1790 to 1808 Dr. Rush gave one or more lectures every year on the same subject in Philadelphia and these became condensed into a book which was the first medical literature on the subject. From that time up to the present it is startling to think how few if any the medical men have ever considered the dangers of spirit and drug taking of sufficient practical interest to make it the subject of teaching to medical students. The fascination of new topics along bacteriological lines and new surgical procedures have overshadowed almost every other subject and the student at graduation, however learned he may be in these particulars, has little or no training concerning the practical facts of spirit and drug poisoning. He must pick these up outside and failing to do this opens a door for quacks, who find a rich field for practice. A very large proportion of the medical graduates of to-day know but very little more than the symptoms of acute poisoning from narcotic drugs and by what means they can be overcome. They accept the theory which directly or indirectly is supported by the professor and family physician on questions of alcoholism and drug taking as extreme views that are more or less unreliable. The laymen and reformer and even a few physicians who urge the danger of spirit and drug taking are not expressing scientific views but only impressions that are unverifiable. The student discovers that alcohol, taken on social occasions and at banquets, gives a certain exhilaration that is very pleasing. Later he realizes that narcotic drugs have a sort of comforting, quieting effect on his brain and organism that are equally pleasing. From this he reasons that these are all excellent drugs, that it is only the misuse of them that is perilous, and often this fact makes a permanent impression on his whole life. For a time, if the circumstances are favorable and the opportunities present themselves, he makes continual experiments to find the safe use of these drugs in his own personal experience, not only in his practice but for his own general comfort. After a time the first effects wear off and only painful sensations follow. Then there may be conditions of immunity in which spirits or drugs may be taken a long time, but

sooner or later some intercurrent disease breaks out with chronicity and death, which is ascribed to exposure, while the real causes are overlooked.

This is by no means an uncommon experience. The diseases and disabilities of physicians in middle life are very often associated with and proceed directly or indirectly from some form of spirits or narcotic drugs taken on special occasions to relieve special conditions. Often they begin this in early life, particularly when medical students, and use the drugs off and on, until finally they are used continuously. Not unfrequently, physicians awaken in early or middle life to the fact that they are unable to extricate themselves from what they term the habit of drinking or using drugs. They make great efforts to overcome this and if successful realize how much loss they have caused to their vitality, and permanent lowering of efficiency both physical and mental.

Medical colleges are certainly at fault for not incorporating the great questions of alcoholism and drug taking among the topics which they teach their students to be familiar with. Physicians should be trained to understand the degenerations that come from the continuous poisonings of narootic drugs, and their effects on mind and body, cumulative and concealed. These are topics which are pressing for solution, and laymen and philanthropists often look in vain to learned physicians for instruction and help on these great questions.

Many exact scientific studies into the causes of disease come back to alcohol and drugs as primary and distinct factors. How to prevent and treat these causes is a purely medical topic, requiring medical training and skill to discern the real causes and conditions and train the mind and body to overcome them. If the therapeutists in colleges would associate, with their excellent lectures instruction on narcotics, the dangers which are likely to follow from indiscreet use, also the susceptibility of certain organisms to become diseased by these agents, they would supply a great want which physicians everywhere realize. Innumerable medical men in every section of the country are consulted by laymen as to what can be done to relieve the sufferings of the victims of alcohol and other narcotics and what measures can be used to prevent their development and growth, but they are utterably unable to give anything more than the most general counsel, and that is not always of a practical character. Many physicians turn these cases over to quacks, believing that there is a large moral element in their conditions which irregulars or clergymen can treat as well as they. This is fatalistic and is followed by an increased army of degenerates and chronics that could and should have been prevented from becoming such by proper treatment at the right time. Young men starting in practice are often called in to treat acute cases of alcoholism and drug taking. The inference is that they are better trained than the family physician, and being strangers there is less danger of publicity in employing them than one who knows the family well. The young physician is without any practical knowledge, except what he may have learned in some hospitals, and this is often of the most vague and informal character. In desperation he gives opium or its alkaloids. The results, if good, are accidental. If the patient continues to employ the physician he becomes disgusted and soon turns the patient over to another whose ignorance may be more dense than that of the old family physician. Had the original medical attendant received some proper training in the college he would have been able to retain a patient that now goes wandering around from one quack to another until he dies. The family physician in the course of years has picked up some knowledge concerning such cases. Much of this may be influenced by his own personal habits, and when this fails to become practical he turns also to the quack. Thus an increasing army of patients are neglected and lost to the regular profession, patients who could have been treated successfully and cured to a large extent.

The intense conservatism of medical colleges and medical teachers has closed the door on many a field of practice that their students could and should have occupied. The post-graduate schools ought to recognize this field of psychoses and give practical instruction that could be put to service in every community in the country. Every active physician comes in contact with spirit and drug takers and the laymen of his community turn to him with increasing frequency for counsel and instruction as to what shall be done. He is unable to give it, and this brings wandering irregulars and enthusiastic reformers into the community who try to teach the great doctrines of preventive medicine concerning spirit and drug taking. The family physician is ignored. He of all persons who should be best able to advise and counsel and give lectures to his patrons is silent. The fault is in the medical colleges and should be remedied.

Alcohol and syphilis are recognized now as very widespread causes in a great variety of neuroses and psychoses as well as acute inflammations. Syphilis has attracted some attention and is the subject of lectures in colleges, but alcoholism is still regarded with indifference and is practically unknown. What the medical student of to-day needs is practical instruction as to how to meet and treat conditions that are common and how to advise and counsel on the great hygienic questions of the day. His whole future turns on his practical knowledge of the great questions of science that call for solution in every community. Spirit and drug-taking are two of these topics and should be taken up in every medical college in the country.

Walnut Lodge Hospital.

PREVENTION AND TREATMENT OF THE DEFORMITIES IN ANTERIOR POLIOMYELITIS.*

By JACOB GROSSMAN, M.D.,

ASSISTANT ORTHOPEDIST, LEBANON HOSPITAL, O. P. D.

Anterior poliomyelitis is rarely diagnosed in the acute febrile stage. One usually makes the diagnosis after the paralysis appears. Even though the diagnosis is made early, very little can be done at that time to prevent the later damage. Flexner has shown that hexamethylenamine is of greatest value before any of the symptoms appear; after the infection occurs, it has very little or no effect. It should be used, nevertheless, as it liberates formaldehyde, which may act as an antiseptic and bacteriocidal agent in the nasal cavity and cerebrospinal fluid.

In the acute stage or stage of onset, there are usually fever, headache, vomiting, intestinal dis-

*Read at the Bronx County Medical Society, May 19, 1915.

turbances and very often severe pain. According to Flexner, this pain is due to the involvement of the intervertebral ganglia. The treatment of this stage consists of rest, freedom from excitement and activity, and recumbency for a period of days or weeks. All cases should be kept quiet until the tenderness has disappeared.

In a few hours or a few days after the onset of the disease, paralysis appears. This paralysis is usually of the flaccid type, reflexes are lost ,and the reaction of degeneration soon appears. At the onset, the paralysis is usually much severer than the one that persists. One or more limbs may be affected. The lower extremities are far more often paralyzed than the upper (Whitman).

The affected parts are tender to the touch and motion. This tenderness may persist for several weeks, during which time it is best to leave the patient alone except for the prevention of the contractures.

Prevention of deformities: Deformities are not always caused by a permanent paralysis, but may be caused by the force of gravity, by the unopposed action of the active muscles and by functional use. In a large number of cases, one or more of the dorsi-flexors of the foot are weakened or paralyzed and the foot drops under the influence of gravity; if this attitude is permitted to persist, the muscles on the posterior aspect of the limb accommodate themselves to it and become shortened. Hence to prevent this deformity the foot should be kept at a right angle to the leg during this painful stage. A very good and simple method is to have the soles of the feet rest against a box covered with a blanket and placed against the foot of the bed. Other means which have proven of value are the application of a light Volkman's splint, or a posterior moulded plaster of Paris bandage. By these same means splints, braces, plaster of Paris bandages, the deformities at the knee (which is usually a flexion deformity), and at the hip (which is usually a flexion and abduction deformity of the thigh on the body, due to a contraction of the fascia lata) can be prevented. This treatment will allow the patients to recover a considerable degree of muscle power which would otherwise be lost entirely or regained much later by operative procedures. Massage, passive movements and electricity should not be used during this tender stage. Frequent change of position is desirable so as to prevent pressure sores. Keeping the patients out of doors is very beneficial.

Treatment of the deformities: After the tenderness is gone, active treatment should be begun—the sooner the better. The resistance of the patient should be built up with general tonics, fresh air, and good food. Massage, electricity, and muscle training should be given until the period of spontaneous repair has passed. This period is an indefinite one, and by most authorities is to last between one and two years.

The massage should be given daily for fifteen minute periods; it may be given either with an electrical vibrator or manually, preferably the latter. The mothers are taught how to massage the affected parts at home, so that no time is lost. The benefits derived from massage are: (1) The improvement of local and general circulation. (2) The prevention of muscular deterioation.

In regard to the electrical treatment, there are a great many authorities who claim that little benefit is derived from its use; many others, however, lay much stress on its use. In our clinic at the Lebanon Hospital, we have found it of some value; but certainly not the specific benefit claimed by some orthopedic surgeons. Static electricity is best, because it improves the life of the muscles and nerves, without overstimulation. Should overstimulation take place, much serious damage can be done. Hence it is best to give these treatments for short periods of time, about five to ten minute seances three times a week, alternating them with massage; the current used should be the weakest that will produce a contraction. Where static electricity cannot be had the galvanic current is next best. The faradic current is useless and can only do harm by overstimulating the muscles and nerves. Hydrotherapy is of some benefit, as it increases the circulation and stimulates the growth of the limb. The affected part should be immersed in water 95-100° F. every night for fifteen to twenty minute periods.

Muscle training is the most useful. It is based on the fact that all the motor centers in the cord have not been destroyed, unless the destruction in the cord has been a very extensive one. Hence new connections and new paths for sending a motor impulse from the brain to the muscle are produced. Passive movement is the first one done. It should be done slowly and to the fullest range of motion possible, pausing at each extreme and returning the part to the normal position when the motion is finished. The same movement is then performed against slight resistance offered by the patient, the resistance being gradually increased. The patient then performs the movement himself while the physician guides it along the proper plane. The guidance is gradually diminished and as the patient becomes more proficient the guidance is removed entirely; finally the movement is done against the resistance of the physician; the resistance may be varied according to the degree of paralysis present. In addition to this muscle training, a good means at our disposal is to get the patient on his feet as soon as possible after the painful stage and in that way have him use his muscles by his own efforts, to walk and balance. The sitting posture is most adaptable for training the muscles of the spine and trunk.

If there is fixed deformity, by which is meant if the functions of a joint are limited and there is restriction of its arc, this deformity must be overcome before any treatment can be satisfactory. The deformities usually met are footdrop or pes equinus, flexion deformity at the knee, flexion and abduction deformity at the hip. In the spine the most troublesome deformity is lateral curvature. At times if the paralysis of the posterior group of muscles is extreme, kyphosis may be induced. In the shoulder the deformities are usually slight, because the part is not subjected to the strain of weight bearing and because the force of gravity is opposed to muscular contraction. The best way to overcome these contractures or fixed deformities, is by gradual forcible stretching and the subsequent application of plaster of Paris bandages, splints or braces. One must always bear in mind the possibility of injuring nerves and blood vessels when stretching a limb. If the contracture deformity is too powerful to be controlled by these means, tendon lengthening by either the open or subcutaneous method, myotomy with the subsequent application of plaster of Paris bandages should be resorted to. These preliminary steps

should subsequently be followed by mechanical or operative measures. A few words about lateral curvature of the spine. This deformity should be looked for in every case and where present, especially low down in the spine, forcible correction, and retention by a Kleinberg brace, or an Abbot jacket, perferably the former, should be done. The brace or jacket must be applied early and worn persistingly because the cause of the deformity which is the unilateral paralysis is always present to aggravate the condition. If after about one or two years of conservative treatment cases do not respond satisfactorily they are then ready for radical operation.

Operations are undertaken (1) to correct the fixed deformity when present; (2) to improve the muscle function, and (3) to secure stability of useless joints.

1. The correction of fixed deformities has already been discussed.

2. The improvement of muscle function is usually accomplished by transplanting the tendon of a sound muscle for that of a paralyzed one. It is best to defer this operative procedure for a period of at least one or two years after the onset of the paralysis as within that time all spontaneous recovery of function should have taken place. Good function in the limb operated upon can be expected in about six months. One must always bear in mind that massage, muscle training, active and passive motion of the tendon, free from body weight, should invariably precede subjection of the joint to the heavier strain of the body weight.

3. To secure the stability of flail and other more or less useless joints: This is usually done when so many muscles are paralyzed that transplantation cannot be undertaken. Arthrodesis or the production of artificial ankylosis, is one of the methods used. It is of greatest service at the ankle joint where it may serve to fix the foot at a right angle to the leg. Arthrodesis should not be done in children under fourteen years of age, where the knee cannot bear the body weight, or on the knee in children on account of the interference with the epiphyseal growth. Astragalectomy, as advocated by Whitman, has been performed in paralytic calcaneous with excellent results. Osteotomy in some instances, especially in extreme deformities in the adult, has proven useful in overcoming resistant distortion. The silk ligament suspension operation as advocated by Bradford and Allison and reported upon favorably by Ryerson, is especially of value in foot drop.

Nerve grafting, as advocated by Spitzi and others with the aim of restoring muscular power in paralyzed muscles by uniting the inactive nerve with one which is still active, has been performed with encouraging results but the operation is still in the experimental stage.

In conclusion it may be said if a case of anterior poliomyelitis is seen early it is possible by mechanical means as splints, braces, manipulation, muscle training and massage to prevent the occurrence of contractures. In the later stages, we have at our disposal means such as manipulation, tendon transplantation, tendon fixation, arthrodesis, and various bone operations to entirely correct some and improve probably the majority of the deformities that are usually met with.

I wish to thank Dr. S. Kleinberg for his kind suggestions.

ECZEMA AND THE BULKLEY RICE DIET.

By F. TWEDDELL, M.D.,

SUMMIT, N. J.

The etiology of eczema is very imperfectly understood by the average general practitioner; this is due to the teaching of the textbooks, which give any number of "predisposing and exciting causes," but no definite proofs. Six cardinal symptoms are popularly supposed to be *always* present, namely erythema, itching, moisture, crusts, fissures and infiltration.

For many years I have been a sufferer from a form of eczema, seldom recognized by the general practitioner and not always by the dermatologist. The first sign was itching and sweating between the toes, sometimes followed a day or two later by the appearance of a vesicle, which itched incessantly. Most vesicles, when opened, will discharge their contents for awhile and then dry up. Not so, however, in this variety. When opened, they oozed for some time, then closed up again as if they had never been touched. Next the vesicles formed between the fingers. These persisted for months, accompanied by intense itching. Opening up the vesicles in the hope of assisting them to dry up did not improve matters, for they discharged for a long time or formed new walls.

For nearly twenty years I have been afflicted with this annoying condition. Curiously enough, these vesicles appeared and usually persisted throughout the warm months of the year. On the other hand, during the winter months, the vesicles disappeared, and were replaced by fissures, usually on the tips of the fingers just below the nails, at other times on some other part of the hands. The first sign was a small painful point, like the mark left after using a hypodermic needle. The next day the skin had split open about ½ mm. wide, and three or four mm. long. The fissure did not itch, but was very painful.

In October, 1914, the vesicles spread to the palms and to the dorsum of the hands, with the formation of crusts, fissures, and a serous discharge. There was no rash on any other part of the body. It was now high time to see a dermatologist and I decided to consult Dr. L. Duncan Bulkley of New York.

On October 29, after taking a careful history, and examining me thoroughly, Dr. Bulkley put me on three meals a day, consisting of nothing but hot boiled rice, bread and butter, and water. My weight was then 185 pounds. I was advised to examine a specimen of my urine and found that it showed an excess of indican.

It is well to mention here that I was not only a great meat eater but also a heavy eater and that I did not get enough exercise in proportion to the intake of food.

When I reported myself at Dr. Bulkley's office a week later, November 5, the condition of the hands had improved, and the itching of the toes had entirely stopped. However, a maculo-papular rash had appeared on the legs, thighs, arms, and trunk, showing that the excess of protein had not yet been eliminated. My weight now was 179 pounds. I was placed on rice diet for another week.

At my third visit, November 12, after two weeks' treatment, the rash on the hands had greatly improved, but the erythema and papules on the limbs and trunk were at their worst and the itching was

well nigh intolerable. I was now allowed a purely vegetable diet but I was told to set apart one day in the week for a rice diet. On November 13, I dined with some friends, drank one cocktail and some light French wine and ate a rather thick piece of tender steak. The effect of this meal was very striking, for within two hours the itching became intense, the erythema looked angry, and the papules became more elevated. The rash reappeared in places where it had disappeared.

On November 17, at 5 A.M., I returned from an obstetrical case, and took a small bottle of beer and some crackers before going to bed again. Waking up about 9 A.M. I was thunderstruck at my condition, fissures had made their appearance on the fingers and on the palms, and crusts were scattered over the dorsum of both hands. The rash on my limbs and trunk broke out anew. This experience showed plainly the overstimulating effect of a small amount of alcohol. The former experience of November 13 I attributed entirely to the steak. The next day, November 18, the condition seemed a little worse. On November 19, I saw Dr. Bulkley. There was slight improvement as far as appearances went, but the itching was intolerable. I noticed, too, this day that I was intensely sensitive to the cold, and did not feel comfortable in the house until the temperature was raised to 84° F. I was ordered on a rice diet for five days. Weight 182 pounds. On November 20, the rash had improved greatly. The right hand was almost normal, except for healing fissures; the left hand had improved, too, but the areas occupied by the interossei muscles were still red but of a dull color. The rash on the limbs and trunk had diminished and the itching was much less. November 24: Right hand practically normal. November 25: Fissure appears on tip of middle finger of right hand. November 26: Took some turkey for dinner. November 27: Left hand practically normal. Rash on trunk and limbs persists but the itching is much less. November 29: Hands normal, rash on trunk and limbs improving, points of selection being confined to the skin over the extensor muscles of the forearms and arms and over the insertion of the deltoid. The rash entirely covered the leg and thigh but the last spot to disappear was on and below the posterior superior spines of the pelvis. On the trunk in front the rash never extended above the umbilicus, and behind it occupied the lumbar region and the shoulder. The rash fortunately never appeared on the neck and face. This day I dined at a club, ate everything in moderation, which had no effect on me the next day. Dec. 4: Rash almost gone on trunk and limbs. Took salmon for lunch and dinner. Dec. 5: Effect of salmon plainly seen today; erythema, papules, and itching reappear.

From this time on I took chances in the selection of my food, eating as much protein in the shape of fish, meat, and cheese as I dared without making conditions worse. Owing to this, the erythema and papules did not entirely disappear for a couple of months. I am sure now that had I confined myself to Dr. Bulkely's rice diet or purely vegetable food, my condition would have improved far more rapidly.

I wish to emphasize the following points:

1. That itching, sweating toes, with or without vesicles between them, signify eczema, from a diet too rich in protein or stimulants. Itching cannot be attributed to tight shoes, for I wear "Ground Gripper" shoes, which are very wide.

2. That itching vesicles on the interossei muscles or between the fingers, signify eczema.

3. That fissures on the fingers or other parts of the hand signify eczema.

4. That the itching vesicles usually appear during the warm months of the year, and the fissures during the cold months, and that the patient feels the cold intensely.

5. That a diet rich in protein or stimulants is the sole cause of this form of eczema.

6. That consequently the rice diet of Dr. Bulkley, followed by a purely vegetable diet, is the only rational treatment.

My gratitude and thanks are due to Dr. Bulkley for his patience, kindness, and interest in my case.

15 NORWOOD AVENUE.

A SIMPLE TREATMENT FOR IVY POISONING.

BY JOHN E. LANE, M.D.,

NEW HAVEN, CONNECTICUT.

ONE of the most frequent forms of dermatitis venenata, ivy poisoning, affords an excellent illustration of the statement that "the efficiency of the treatment of a disease is inversely proportional to the number of remedies recommended." Hyde remarked that "many topical remedies have been vaunted as specifics for this disorder, from the brine of a pork-barrel to a decoction of the leaves of the plant itself."

While it is probable that comparatively few physicians have tried the two "specifics" mentioned, there are few who have not tried with disappointment the "many topical remedies" which are not mentioned by name. As the list of remedies remaining in the text-books that refer to this disease is somewhat long, the physician is puzzled as to which to try first, and frequently tries one after the other till the trouble subsides.

For some time I have used in most cases one thing only, and the relief, both to physicians and patients, of using *one* simple and fairly efficient method, has been so noticeable in a large majority of the instances in which it has been recommended that I am led to call further attention to it, making no claims for its novelty, for its being a specific, or that it is the *best* method of treatment. Still it has some advantages. It is cheap, it is harmless in any location, it is clean (something that is not true of many of the mixtures commonly used), it is always easily accessible and easy of application, it is suitable for any stage and for any case extensive enough to require much treatment, and it gives as much relief and comfort to the patient, and hence is as little unsatisfactory, as anything I have tried. The comfort of the patient is the chief indication to be met as the disease is self-limited.

I have had no experience with trying to abort the disease and do not remember having seen any authentically aborted cases of it. I have had no experience with ointments in fully developed cases, except to remove them. They are not indicated as they are hard to remove without damage to the underlying skin and if they become adherent they favor the development of infections.

The treatment is this: The affected areas are loosely covered with two or three thicknesses of gauze or cheesecloth, which is kept continually moist with a solution of boric acid, the strength of which is unimportant. The gauze is frequently changed in any case, but the frequency depends

somewhat upon whether there is much oozing from the blebs. The larger blebs are opened but it is unnecessary to touch the smaller ones. If the gauze is used more than once it is rinsed and boiled before it is reapplied. As the largest number of these cases occur during the hot weather it usually adds to the comfort of the patient to keep a small piece of ice in the solution so that it may be applied cold. This is usually the whole treatment, but in cases where the itching is very intense some additional relief may be obtained by gentle sponging with a weak solution of alcohol when the gauze is changed. A simple ointment may be used for protection after healing has begun and the skin has become fairly smooth.

The advantage of this treatment in addition to those already mentioned is that no trauma is inflicted and that if powder settles on the skin from evaporation of the liquid it is easily dissolved at the next application by using a more dilute solution.

PROFESSIONAL BUILDING.

A NEW WAY OF STAINING CELLS IN THE CEREBROSPINAL FLUID.

BY B. LEMCHEN, M.D.

DUNNING, ILL.

CHICAGO STATE HOSPITAL.

WHILE the stain that I have been using for cerebrospinal fluid is not new, the method in which I am doing it is new. I simply take benzidine and make up a 2 per cent. solution in glacial acetic acid, which I call solution number one. The other solution is hydrogen peroxide. When I am ready to count the cells I take a small test-tube and put in solution number one and an equal amount of solution number two, mixing the two together. I take a pipette and draw up the stain to .5 and then draw the spinal fluid to the 11 mark. The two are mixed together and then put on the counting chamber. I use the Fuchs-Rosenthal, but any other chamber would do just as well. By this method the red blood cells are stained blue and the polymorphous cells are stained a light yellow, while the nucleus is visible by having blue granules in it. Parts of the periphery are stained blue. In the lymphocytes, the periphery is stained dark blue, looking like a dark blue ring. The middle of the cells is not stained, except in places there are blue granules. In the plasma cells, the periphery is stained dark blue, almost black, and the middle of the cell is all clear—does not take any stain at all.

Now, it is hardly necessary to refer to the value of counting cells in cerebrospinal fluid, because wherever the meninges are involved there is always an increase of cells. While some authorities claim that from one to five cells per c.mm. are found in the normal and that we find an increase in cells (lymphocytes) in tuberculous meningitis and that we also find an increase of cells (polymorphous leucocytes) in any other form of meningitis, all authorities agree that plasma cells are found only in syphilitic involvement of the meninges. Of course, men of much experience claim that they could recognize plasma cells even with the ordinary stains that have been in use; for instance, methyl-violet or the Wright stain, and acetic-acid; but a good many physicians will hardly be able to recognize them, and, in fact, with the old stains it is sometimes very hard to tell whether we have a red blood cell or a lymphocyte.

Therefore the value of a simple stain that will differentiate the cells in the spinal fluid is obvious, as blood is sometimes, or a good many times, mixed with the fluid in such a small amount that one could not tell it with the naked eye.

In addition to this I have found that with the use of this simple stain we can differentiate the cells even with a low power of the microscope. In large hospitals, where there are many cell counts to be done every day, I believe it will prove of some value to employ the stain in the way I am using it in our laboratory at the State Hospital in Dunning.

Medicolegal Notes.

Opinion Evidence as to Cause of Death.—In an action on an accident policy for the death of the plaintiff's husband, which had taken place when he was sawing upward through planking, in a cramped position, on a hot day, the appearance of the deceased was that of one who had died of a ruptured artery, according to expert medical testimony. It was held that judgment for the plaintiff could not be based on such testimony alone, which would require a further inference that the ruptured artery resulted from accident, based on the expert's inference that the death resulted from a ruptured artery, and the jury may not pile inference upon inference. The burden was on the plaintiff to show by competent evidence, to a resonable certainty, that the accident was at least an active agent in producing the death. —Wright vs. Order (Mo.), 174 S. W. 833.

Indorsement of License of Another State—Examination in English.—In mandamus to compel the New York Board of Regents to indorse a license granted the relator to practise in the State of Michigan, it appeared that the relator was an Italian and a graduate in medicine of the Royal University of Palermo, Italy. After coming to this country he became a resident of Buffalo, N. Y. Desiring to practise medicine in the State, he found that he would have to pass a regents' examination in English. He thereupon applied to the Michigan State Board of Registration for admission to the examinations conducted by that board, and having passed these examinations, was granted a medical license by that board. That examination was taken in Italian, English not being a requirement in Michigan. Within a few days after that he made application to the New York Regents for indorsement of his Michigan license. They notified him that his application had been returned to the Michigan board with the request that it withdraw its indorsement, on the ground that by going to Michigan for the examination the relator had avoided the specific requirement in New York State that in order to be admitted to its licensing examination he would have to pass the Regents' examination in second year English for foreigners. The Michigan board withdrew its indorsement. The relator maintained that he was entitled to the indorsement because the Michigan board was one "maintaining standards not lower than those" prescribed by the New York board. It was held that, while the discretion given the Regents in according or withholding the indorsement of a license cannot be arbitrarily exercised, it was not an improper exercise of such discretion to refuse to indorse the relator's license, though the Michigan board had been registered as maintaining a standard not lower than that required by the New York Public Health Law.

The only registration of the Michigan board was effected, if at all, by a reciprocity agreement between the authorized officials which authorized the Board of Regents to request a consideration of any certification by the Michigan board of a license granted by them if the Regents had any reasonable doubt of the qualifications of an applicant. If this agreement effected a registration of the Michigan board within the New York statute, the registration was subject to the provisions of the agreement, while, if the agreement was not a statutory registration, there was no registration authorizing an indorsement of the license; so that in neither case was the relator entitled to have his license indorsed.—People v. McKelway, 163 N. Y. App. Div. 286, 148 N. Y. Supp. 818.

THE BROADENING SCOPE OF THE BINET-SIMON TESTS.

THE ability to apply some sort of rule or measure to problems which confront us is very gratifying to one aspect of human psychology. It does away with the feeling of insecurity. Hence the pedantic exactness of neurotics, according to Alfred Adler of Vienna, who says that they suffer from a chronic feeling of insecurity and seek a sense of security by endeavoring to gauge everything exactly, to drop hitherto unknown elements into definite mental compartments. The popularity of such tests as those of Binet-Simon is due largely to this manner of thinking. Intended by their originators only for juvenile use they have been applied by other investigators to aid in the solution of certain puzzling adult conditions. Thus the adult offender, who does not show any gross psychotic symptoms, is subjected to these tests and often found wanting.

W. C. Sullivan, writing in the *Lancet* of March 23, 1912, reported the use of these tests on a number of prisoners with interesting results. He especially recommended them for application to those adult delinquents who show a superficial liveliness and even wittiness which is apt to mislead untrained observers and cause them to overlook intellectual defects. Dr. Sullivan advises certain alterations in the tests to make them more suitable for adults.

Following in his footsteps M. Hamblin Smith (*Lancet*, July 17, 1915) has applied the tests to a number of prisoners. He divides his cases into "feeble-minded" and "not feeble-minded," but does not make his distinction quite clear, although he is careful to state that by "not feeble-minded" he does not necessarily mean mentally normal. Like most investigators who have used these tests on subjects other than those for which they were intended, Smith recommends various modifications of them. He thinks that they are useful only for males of 25 years and below and for females of 30 years and younger. Above these ages, he asserts, cooperation is difficult to obtain and the subject is more inaccessible. He says that the failure to reach any given standard of intelligence is not of itself sufficient reason for regarding the subject as feeble-minded.

Another field for the Binet-Simon tests is exploited by Louis Wender (*N. Y. Medical Journal*, March 6, 1915), who thinks they are valuable in the senile psychoses, especially where the hallucinatory and delusional fields are not prominent, but where the mental disorder consists rather of a simple deteriorating process. Wender examined thirty old men of this type. He found that the longer the disease had been in existence the more pronounced was the retrogression. After suggesting several revisions of the tests the writer gives two instances where they may be of value in seniles. He says that where it is difficult to make a diagnosis between arteriosclerotic dementia and senile dementia failure to pass these tests speaks for the latter condition. He also suggests that they be applied to old persons in a community who have deteriorated to the extent that they are not capable of handling their financial affairs and yet who do not show tendencies which would necessitate intramural care.

The problem of the amount of deterioration which exists in chronic alcoholics is often puzzling, and Dr. D. Percy Hickling (*Washington Medical Annals*, May, 1913) thinks that it may be solved by these tests. He says that often a slight degree of deterioration is present in the chronic alcoholic, so slight as to be imperceptible to his associates and yet real enough to impair his social efficiency. Failure to retain positions which he formerly held often drives him back to alcoholism as a refuge. This deterioration may be discovered by the Binet-Simon tests which Hickling recommends applying to all alcoholics who seem to be failing in efficiency. He states that these tests do not show accurately the degree of mental deterioration, but they do show that such exists.

Thus we have many suggestions for the use of the Binet-Simon tests in other ways than for children. Certainly they have the advantage of being simple to apply and of being readily usable by any physician even though he have no psychiatric training. It is only required that he follow closely the directions given by the originators. Judging by the views of those investigators who have worked with them in alien fields we shall have in time complete modifications of the Binet-Simon tests to fit such types as the heboidophrenic, the alcoholic subject, and the senile dement.

FUNCTIONAL DISEASES OF THE ARTERIES.

RELATIVELY scant attention has been paid to the diseases of the arterial system, particularly those of functional nature, when compared with the vast amount of study that has been devoted to the functional diseases of the heart. The former are really three times as common as the latter, as pointed out by Sir Lauder Brunton in the *Lancet*, July 24, 1915. The functions and the disturbances of the arteries may be studied independently of those of the rest of the cardiovascular system. One function of the arteries usually overlooked is their ability to pass blood on into the veins by means of peristalsis. From the days of Hippocrates and of Morgagni abnormal pulsation of the abdominal aorta has puzzled clinicians. Although the pathology of this condition is still veiled in obscurity, Brunton believes that Morgagni was right in ascribing it to nervous irritation. This is probably produced re-

flexly through the solar plexus by some irritation in the stomach or duodenum and occurs especially in cases in which there is a suspicion of ulcer. A pulsating aorta is to be differentiated from aneurysm by the fact that in the former the pulsation is only in one direction while in the latter the pulsation is in all directions.

Abnormally great pulsation is also observed in other arteries, as the innominate, subclavian, and carotid. A frequent throbbing of the large arteries is a common accompaniment of exophthalmic goiter. Brunton believes that the throbbing of the carotids in this disease is due not only to longitudinal elongation but also to lateral expansion and is a manifestation of hyperthyroidism. The throbbing of the carotid on one side in migraine shows that the condition depends partly at least upon the nervous system, although the possibility of a toxemic element cannot be excluded.

Functional disturbances of the arterial system due to dilatation, as seen in blushing and in the flushes of the menopause, are less common and of less importance than those due to arterial contraction. One of the most characteristic of these occurs in migraine which has been studied exhaustively in his own case by Brunton. He finds that the causation of migraine is twofold: (1) a toxemia from the liver or intestines, and (2) a local cause, such as eyestrain, dental caries, or nasal or aural irritation. Other conditions caused by arterial contraction occur in the acroasphyxia of various degrees of severity, its most pronounced type being Raynaud's disease. There is no longer any question, he thinks, that angina pectoris is primarily caused by vascular spasm. So also is the "angina abdominis" thus named by Baccelli but previously described by Brunton and about the same time by Huchard as "angina pectoris pseudogastrique." The point is emphasized that in many cases the symptoms of vascular spasm occur although the vessels affected are healthy. As the arteries become less elastic with age the tendency to constriction frequently becomes less marked. But the effects of atheroma may exaggerate the symptoms caused by actual spasm.

THE PROPHYLAXIS OF MUMPS.

Epidemic parotitis has always been regarded as rather of a negligible quantity among the infectious diseases because of its general harmlessness, and it is probably on account of this attitude that so little is known about its etiology and treatment. It is true that, in children at least, it is a comparatively trivial affection and very rarely accompanied by more than a transient discomfort, but in institutions it is apt to occur in epidemics which occasion a great deal of annoyance to the managers and an excessive amount of work to the meager nursing staff. We have no treatment worthy the name, and isolation as a prophylactic measure is made difficult by the long period of incubation.

As a rule one attack of mumps confers a complete and lasting immunity upon the individual, and it is therefore reasonable to suppose that such a person carries in his blood antibodies against the infectious agent. Working on this theory Hess (*Am. Jour. Dis. of Children*, 1915, x, 99) has recently been injecting the blood of immunes into children who had been exposed to the infection. His results are interesting for in no instance did parotitis develop in a child thus protected. From six to eight cubic centimeters were obtained from a vein of the donor with a syringe and immediately injected intramuscularly. The procedure was, of course, guarded by the Wassermann reaction and in no case was there any rise of temperature or local reaction. He found it possible to use as donors patients in whom the swelling had not subsided and the long period of incubation permitted inoculation some time after the exposure. Blood injected in this way should not cause trouble because of incompatibility and the whole process seems to be devoid of danger. It should prove of value, especially in orphan asylums and similar institutions, where a large number of susceptible persons are collected.

A DISSERTATION ON THE DIAPER.

That the dignity of medical science should condescend to a discussion of the correct application of the diaper would seem strange were it not for the usurpation of this function by knowing aunts and wiser nurses, who have really retarded the evolution of this important perquisite of the nursery. The time has apparently arrived for a radical dress reform in this most elementary of all garments. From time immemorial infants have protested loudly and eloquently against the clumsy method of ensheathing a goodly portion of their anatomy, but until now their cry, although heard only too well, has been woefully misunderstood.

Samuel A. Visanska (*Pediatrics*, July, 1915) believes that the ordinary infant's napkin produces across the lower abdomen a constriction, which is responsible for many intestinal and other disorders. As ordinarily adjusted one end of the napkin is pulled sharply from the left to the right side with the result that pressure is brought directly over the sigmoid. This is regarded as one of the main causes of intestinal stasis in infants, being comparable in this respect to the obsolescent abdominal binder. Another effect of the infant's napkin as usually applied is to produce undue pressure upon the soft and plastic pelvic bones. The antero-posterior diameter of the pelvis is slightly lengthened and the transverse diameter is narrowed. The pelvis is further deformed by the greater pressure being produced on its left side. These effects are much more pronounced if rachitis is present. In the infant the fundus of the uterus is on a line with the anterior superior spinous processes and the bladder when full rises a little higher, both of these organs being actually in the abdominal cavity. Over these is brought to bear for a period of eighteen months or more the bulky mass made up of the ends of the napkin pinned together, the pressure of which mass is increased when the infant sits up. Visanska believes that this factor is responsible for a large share of the uterine and other pelvic displacements so common in women. He cites the Indian custom of wrapping about the papoose a soft unpinned

cloth and attributes the proverbial health and easy childbearing of Indian women partly to the looseness of their entire garb from infancy to old age.

The so-called new method of designing and applying the infant's napkin may have suggested itself already to many a resourceful matron. Indeed, it was from one of them that Visanska first got the idea. The plan consists in adapting to the needs of the infant the principle of the ordinary T-bandage. Instead of the napkin being folded in the form of a triangle, it is cut in the form of a T-square a little longer than wide. The napkin is secured by means of two safety pins, one on each hip of the child. This arrangement is said to afford the necessary protection without subjecting the infant to any discomfort or producing any undue compression.

THE ACTION AND USE OF EMETINE IN ENDAMEBIASIS

In view of the increasing rôle played by emetine in modern therapeutics, considerable interest is attached to the study of the mode and sphere of action of ipecac and emetine in the treatment of endamebiasis. Such study is contributed by Randolph Lyons to the *American Journal of the Medical Sciences*, July, 1915. He finds that when these drugs are administered either by mouth or hypodermically they exert their action only after they have been absorbed into the blood stream, and affect the endamebas only within reach of the circulation, namely, in the tissues. The important fact is brought out that endamebas free in the lumen of the intestine are not affected by either the oral or subcutaneous use of the above drugs. Experimental evidence is cited to show that the amebicidal principles of ipecac when taken by mouth are not eliminated in the feces.

Emetine administered hypodermically fails to destroy the vegetative *Endameba coli*, a parasite simply harbored in the intestinal canal. This fact is supposed to argue against the elimination of the drug from the circulation by way of the large intestine. Relapses are attributed to the survival of some of the endamebas, probably through encystment, some of the cysts remaining embedded in the tissues of the gut, and awaiting favorable conditions to become vegetative. In the carrier state the endamebas are simply harbored in the lumen of the gut, and cause no symptoms. In some unknown manner the intestinal mucosa is protected against the penetration of the organism.

In view of the above facts regarding the action of emetine, it is quite obvious that this drug is best administered subcutaneously. Lyons states that small repeated injections are to be preferred, as they are more readily absorbed, and the effect is maintained. In severe cases emetine should be used intravenously. The oral administration of this drug is not advised because of the intestinal irritation that results. Likewise, emetine is not suited for colonic irrigations. Ipecac is preferable for the gastroenteric route.

As regards the dosage of emetine, it is pointed out that in an ordinary case of amebic dysentery an average of one grain daily or less is sufficient. The treatment lasts one or two weeks. If the treatment is too prolonged or the doses of emetine are too large a diarrhea may arise, and may be persistent. Other ill effects may result from such excessive dosage. For the prevention of relapses an intermittent form of treatment should be instituted in every case, even though cysts are not found.

THE PERENNIAL SUBJECT, WAR TETANUS.

The relationship between the coexistence of the main factors of infection in tetanus and actual infection has never been satisfactorily worked out. No doubt infection very often refuses to develop in cases in which every contributory factor is present; just as it does occur not infrequently when apparently none of the critical factors is present, not even a tangible wound. At a meeting last January of the Hamburg Medical Society (*Deutche medizinische Wochenschrift, May 6*), Rumpel stated that he had made bacteriological and inoculation tests of twenty cases of suspicious wounds, but not a single inoculated animal developed tetanus; nevertheless, of the twenty patients, one developed the disease. Fraenkel believes that the tetanus bacillus cannot be demonstrated in wound secretions in ordinary stained smears. To wait for cultures is tedious, but a new method which Rumpel is developing will, he hopes, greatly shorten the period.

It is not impossible that tetanus will eventually be broken up into several distinct types. One of these may be an endogenous type in which nonvirulent tetanus bacilli circulate in the blood and become activated by certain traumatisms which may be very slight. Another type, mentioned in connection chiefly with trismus nascentium, has been termed the neurogenic, because evidences of infection are completely wanting.

The entrance of Italy into the European war will undoubtedly afford us a line on the value of Baccelli's treatment in lowering the mortality of lockjaw. If, as is claimed, tetanus runs a milder course in Italy than in Austria and Germany, this need not apply necessarily to war tetanus, in which so many aggravating causal factors may obtain. The Baccelli method thus far has not received a systematic try-out in the war, having been tested only by certain individuals.

The Function of the Pineal Body.

Until very recently the pineal body has been considered as a more or less interesting vestigial remnant of a third eye and devoid of any importance whatever. The latest interest of the medical profession, however, the study of the internal secretions or of the endocrine glands, or, as one active cultivator of this field would have it, hemadenology, has become so popular and has rewarded investigators with so many new and marvelous facts that the attempt has been made to include the pineal among those glands. Positive evidence has been lacking. A few cases showed precocious sexual development and, at autopsy, tumor of the pineal, but these findings were not regular, for only a small percentage of the cases of tumor of the pineal showed similar clinical pictures. The inaccessibil-

ity of the pineal body has up to this time offered complete obstruction to the experimental study of its physiology. Dandy, however, has devised an operation (*Jour. Exper. Med.*, 1915, xxii, 237) in which he approaches it through the corpus callosum. This procedure is accompanied by very small mortality, so that he was able to study the effects of the removal of the body in puppies. He removed the pineal body from a number of puppies and followed the animals for varying periods of time, the longest being fifteen months. In all of his animals he was able to find no evidence of sexual precocity or indolence, no emaciation or adiposity, no somatic or mental precocity or retardation. His conclusion is that "the pineal is apparently not essential to life and seems to have no influence upon the animal's well being." He used a sufficient number of animals and an adequate number of controls so that there appears to be no reason why his results should not be accepted. It is a relief to find that there is one structure which is not possessed of a mysterious power for good and evil in the economy, and we can therefore dismiss it definitely from consideration as an endoerine organ.

Vaccine and Tetanus.

One of the stock arguments of the antivaccinationists is that cowpox vaccine may become contaminated with the germs of infectious disease and so transmit the latter to the innocent victim of the assault by the vaccinator. It cannot be denied that tetanus has sometimes attacked recently vaccinated persons, and so there is some plausibility in the contention of the anti's that the tetanus spores were implanted with the vaccine virus. The repeated charges that such has been the case have led Dr. John R. Anderson, director of the hygienic laboratory, U. S. Public Health Service, to undertake a careful investigation of all cases of tetanus following vaccination reported in the past ten years and he has endeavored to collect accurate data concerning such accidents. The results of this investigation and of a series of animal experiments seem to warrant certain conclusions, of which the following is a summary (Public Health Reports, July 16): (1) It is difficult, if not impossible, to produce tetanus in susceptible animals by vaccination with virus containing large numbers of tetanus organisms which have been purposely placed therein. (2) In view of the failure to demonstrate tetanus organisms in the large amount of vaccine virus specifically examined for this purpose, it seems exceedingly improbable that vaccine virus as sold in the United States contains tetanus organisms. (3) From 1904 to 1913, inclusive, over 31,000,000 doses of vaccine virus were used in the United States. Yet information was obtained of only forty-one authenticated cases of tetanus occurring subsequent to the operation. From this it is concluded that had the virus used during that time in the United States been at fault many more cases of tetanus should have followed vaccination. (4) In view of the large number of vaccinations, about 585,000, done in the United States Army and Navy, and the absence from them of a single case of tetanus following the operation, the cases of tetanus following vaccination in the country at large were evidently not due to infection contained in the virus. (5) The average period from vaccination to onset of symptoms of tetanus in 83 cases was 20.7 days, while the average mortality of 93 cases was 75.2 per cent., this being slightly higher than the mortality of cases of tetanus due to other causes with an incubation period of ten days or less. The conclusions based upon these studies were that in case of tetanus occurring 15 or 20 days subsequent to vaccination the infection is not received through the vaccine virus, but in all probability is received from outside sources about the tenth day or later after vaccination. The infection with tetanus is a contamination of the vaccination wound, such as may occur in the case of any other surgical or accidental wound not properly cared for.

A New Disease?

It would be difficult to make the well-informed clinician believe that he could encounter a number of cases of disease presenting the same syndrome which he would be unable to identify and which, moreover, could not be classified even when the best professional advice was secured. And yet this is happening now among the soldiers in northern France, according to the *British Medical Journal* for July 17. For the past three months there have been observed numerous cases of a disorder somewhat like subacute nephritis in its manifestations. Dropsy is sometimes present and the urine contains albumin and casts. It does not appear to be infectious or contagious and the medical authorities have been unable as yet to determine what are the predisposing causes. Naturally there has been a great deal of theorizing. One explanation was that it was an Oriental disease, something on the order of beriberi, but this theory was discounted by the fact that it was not prevalent among the Indian troops. Moreover, as has been proven by Heiser and others in the Philippines, beriberi is dietetic in origin and the soldiers suffering from this strange malady have been shown to have had the same fare as the others. A suggestion which obtained some favor for a time was that these were cases of unrecognized scarlatina, but this has since been disproved. Some observers hold that it is an autointoxication due to the intestinal stasis which necessarily develops when men are subjected to prolonged periods of duty in the trenches and elsewhere. Some authorities saw features in it analogous to forms of metallic poisoning, and with this idea in view have made searching analyses of the food, water, and the patients' urine. Whatever may be the cause of this new disease, it does not seem to be very serious except in its temporarily incapacitating effects, and it is probable that a further period of observation will clear up its etiology.

Experimental Infections and the Respiration.

Very little work has been done upon the subject of the effect of the entrance of bacteria or of bacterial toxins into the body upon the respiratory rate and rhythm. Such an investigation has been conducted by Carmelo Cafiero and Giovanni Lorenti (*Pathologica*, July 1, 1915), who studied the effect of both anaerobic and aerobic bacteria and their toxins upon the respiratory center. They found that immediately after the injection of living anaerobic or aerobic bacteria there is an increase in the frequency of breathing. If. however, these germs are first killed the respiratory rate is unchanged or diminished. The respiratory effect is first shown at the end of half an hour following the injection. In other experiments in which living or dead aerobic

germs were injected it was observed that several hours preceding the death of the animal there occurred a further increase in the frequency of respiration followed by a progressive diminution in the latter. At the same time there occurred an increasing amplitude in the respiratory wave. The greatest diminution in the rate of breathing was observed to occur three or four hours after the injection. In some experiments the increased depth of respiration was noted one to one-half hours following the injection. The general conclusions drawn from these researches are that living germs, whether aerobic or anaerobic, cause at first an excitation of the respiratory center; that such property is not possessed by the same microorganisms if killed; that both living and dead aerobic microorganisms cause an excitation of the respiratory center several hours before death, which excitation soon disappears and is followed by a progressive inhibition of this center; and that none of these effects occur if the bacterial toxins are injected.

News of the Week.

Death Rate of the Canal Zone.—Dr. Wm. F. Mason, chief health officer, in his report for June states that the total number of deaths of employees of the Canal Zone during that month was 15; of these, 11 died from disease, or 3.61 per thousand, as compared with 2.43 for the preceding month, and 3.28 for the corresponding month of last year.

New York City Death Rate.—During the week ending August 28 the deaths in New York City numbered 1,351, giving a rate of 12.23 as compared with 12.86 during the preceding week and 12.01 during the corresponding week of 1914. The death rate for the first thirty-five weeks of 1915 was 13.64 as compared with 14.10 for the corresponding period of 1914.

Chicago Death Rate.—During the week ending August 28 there were 565 deaths in Chicago, giving a rate of 12.0 per thousand as compared with 12.2 for the preceding week and 12.2 for the corresponding week of 1914.

Typhoid Fever has been prevailing to an unusual extent in and around New York City. In Westchester County 18 cases were reported during the week ending August 28, in White Plains and the neighboring towns. In this city the disease has been noticeably prevalent in Richmond and Brooklyn boroughs. Of 21 deaths from typhoid fever reported during the week ending August 28, 12 occurred in Brooklyn, and 41 new cases were reported there as against 29 in the remaining four boroughs. Some cases have also occurred on the German liners which have been tied up since the beginning of the war in Hoboken.

Cholera.—The epidemic of this disease which has been prevailing in certain parts of Austria seems to be under control of the sanitary authorities, as during the week ending August 28 the number of new cases reported was only 929. Cases of cholera have been reported in Potsdam, Liegnitz, and Frankfort on the Oder, and the Berlin police have ordered people to boil all drinking water, especially when taken from the rivers. Bathing in the rivers is forbidden. Switzerland has instituted a strict quarantine against the disease along its German and Austrian frontiers and is fumigating the baggage of all incoming passengers. A number of sailors on the interned German steamships at Hoboken have suffered from diarrhea and for a time it was suspected that some of the German refugees from China who had been cared for on those ships might have carried with them the cholera bacillus, but a bacteriological examination showed that the cases were of simple diarrhea and not of cholera.

Hay Fever Convention.—The forty-second annual White Mountain convention of hay fever victims was held last week at Bethlehem, N. H.

Opposed to Twilight Sleep.—It is reported that an association to oppose the twilight sleep movement will soon be started by Mrs. Olson of Flatbush, who proposes to interest wealthy women in the anti-twilight sleep campaign and raise money to circulate literature in behalf of the cause. The immediate incentive to the formation of the new association is said to have been the death of a woman in a Brooklyn hospital where she had gone to have a child after the Freiburg method.

Red Cross Surgeons for Germany.—An association has been formed by German residents of New York to send surgeons and medical supplies to the German and Austrian armies. The first unit, under the leadership of Dr. Hermann Fischer of the German Hospital, sailed on Thursday of this week. The supplies will be sent on another vessel under the care of the American Red Cross. Other units will follow as the money is raised for their outfitting.

Health Board Licenses for Cooks and Waiters.—The Health Department of this city has issued an order that all cooks, waiters, and dishwashers in the hotels and restaurants of this city must submit to an annual medical examination. Those who are found to be free from tuberculosis and other infectious diseases and not to be typhoid carriers will receive a license to continue their occupation, the others must seek other work not connected with the preparation of food. There are 4,500 hotels and restaurants in the city giving employment to about 90,000 persons in the kitchens and dining rooms. Among the first 2,000 examined the health officials found two typhoid carriers and over twenty affected with syphilis, tuberculosis, or other infectious diseases.

The Health of Garment Workers.—Officers of the U. S. Public Health Service have been making, as the beginning of a series of investigations of industrial sanitation in this county, an inquiry into the condition of the garment workers in New York City. In all 3,000 workers were examined, 2,400 males and 1,000 females. The investigation of these 3,000 disclosed 13.457 defects or diseases of all kinds, of which 9,451 appeared among the male and 3,916 among the female workers. Only about 2 per cent. of those examined were free from some physical defect or disease. The most common disease was tuberculosis. Of the workers 69 per cent. had defective vision, 26.2 per cent. had chronic nose or throat affections; that 26 per cent. defective teeth, 26 per cent. flat feet, 15.3 per cent. hypertrophied tonsils, and 10 per cent. defective hearing.

Uniform Blind Alphabet.—The work of preparing a new uniform raised letter system for the use of the blind has been begun by a commission recently appointed at a joint session of the American Association of Workers for the Blind and the American Association of Instructors of the Blind. After the commission has come to a definite conclusion a conference will be held with the British uniform type committee when final action will be taken.

Sterilization of Defectives.—A report recently published by the American Eugenic Society recom-

mends the sterilization of an increasing number of defectives each year until the number reaches about half a million, when it is computed that the propagation of the mentally unfit in this country will be practically at an end.

The New York College of Dentistry is about to erect a seven-story building on Forty-second street, east of Second avenue.

Association of Military Surgeons of the United States.—The twenty-fourth annual session of this association will be held in Washington on September 13 to 15, under the presidency of Col. J. R. Kean, M. C. U. S. A. The secretary is Brig.-Gen. Samuel C. Stanton, M. C. Ill. Nat. Guard, Chicago.

Pellagra Congress.—The third triennial convention of the Association for the Study of Pellagra will be held in Columbia, S. C., on October 20 and 21. The secretary of the association and chairman of the committee of arrangements is Dr. J. W. Babcock of Columbia.

The First Wisconsin District Medical Association, meeting at Juneau the second week in August, elected the following officers: *President*, H. B. Sears, Beaver Dam; *Vice-President*, D. Engsberg, Lake Mills; *Secretary-Treasurer*, S. B. Ackley, Oconomowoc. The next annual meeting will be held at Jefferson.

Dr. F. F. Simpson of Pittsburgh has retired from practice temporarily on account of ill health. A hyperglycemia from which he has been suffering for some years is now so far relieved that it is hoped he can take up his professional responsibilities again after a period of complete rest.

Dr. Maude Glasgow of this city has removed to The Vondel, 171 East Eighty-third street.

Dr. C. D. Christie has been appointed director of the Clinical Research Laboratory at the Lakeside Hospital, Cleveland.

Dr. William Evans Brunner has been elected professor of ophthalmology in the medical faculty of the Western Reserve University.

Dr. M. L. Holm, formerly State bacteriologist at Lansing, Mich., has been appointed chief of the Houghton laboratory of the Michigan State Board of Health.

The Alabama State Board of Health.—A favorable report has been made to the Alabama Legislature on a bill which provides for the election of the State Board of Health by all delegates to the Alabama Medical Association, and the appointment of the State health officer by this board.

Marriage and Eugenics.—The *Boston Medical and Surgical Journal* states that, owing to the notable decline in marriages in Wisconsin, since the enforcement of the so-called eugenics law, the law has been amended to make its requirements less rigid, and permitting physicians greater liberty in granting certificates.

Obituary Notes.—Dr. Nelson W. Wilson of Buffalo, N. Y., a graduate of the University of Buffalo, Medical Department, in 1898, attending surgeon in genito-urinary diseases at the Buffalo General Hospital, and a member of the American Medical Association, the New York State and Erie County Medical Societies, the American Urological Association, and the Association of Military Surgeons of the United States, died suddenly while attending a theater in New York, on August 30, aged 50 years.

Dr. Eric M. Lundholm of St. Paul, Minn., a graduate of the University of Stockholm, Sweden, in 1890, chief surgeon of the Bethesda Hospital, St. Paul, and a member of the American Medical Association, the Minnesota State Medical Association, and the Ramsey County Medical Society, died at St. Mary's Hospital, Rochester, Minn., from pneumonia following an operation for stomach trouble, on August 3, aged 57 years.

Dr. Samuel Walter Bragg of Lincoln, Me., a graduate of the University of Vermont, College of Medicine, Burlington, in 1879, died at his home suddenly, from apoplexy, on August 7, aged 55 years.

Dr. Martin Bernard Roddy of Lynn, Mass., a graduate of the Baltimore Medical College, Baltimore, Md., in 1909, and a member of the American Medical Association and the Massachusetts and Essex South District Medical Societies, died suddenly at the Lynn Hospital, following an operation for appendicitis, on August 12, aged 29 years.

Dr. William F. Muhlenberg of Reading, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1872, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Berks County Medical Society, died at his home on August 25, aged 62 years.

Dr. Nathaniel Wallis of Fitchburg, Mass., a graduate of the University of Vermont College of Medicine, Burlington, in 1894, died at the Burbank Hospital, Fitchburg, on August 18, after a long illness, aged 59 years.

Dr. George E. McNeil of Sedalia, Mo., a graduate of the Beaumont Hospital Medical College, St. Louis, in 1890, house surgeon at the Missouri, Kansas, and Texas Railroad Hospital, Sedalia, for twenty-five years, and a member of the American Medical Association, the Missouri State Medical Association, and the Pettis County Medical Society, died at his home on August 15, aged 53 years.

Dr. Alexander Montgomery of St. Louis, Mo., a graduate of the Washington University, Medical Department, St. Louis, in 1856, a surgeon in the United States Army during the Civil War and in charge of the Government Hospital at St. Louis, and for eighteen years on the staff of the St. Louis Department of Health, died at his home on August 12, after a long illness, aged 81 years.

Dr. Henry C. Stearns of Haverhill, N. H., a graduate of the Dartmouth Medical College, Hanover, in 1896, and a member of the American Medical Association and the New Hampshire State and Grafton County Medical Societies, was instantly killed on August 23, when the automobile which he was driving was struck by a railroad train at Woodsville, N. H. His thirteen-year-old son, who was with him, was seriously injured. Dr. Stearns was 49 years of age.

Dr. Isaïe Cormier of Montreal, Can., a graduate of Laval University, Medical Department, Quebec, in 1882, died suddenly, from acute indigestion, at his home on August 17.

Dr. Samuel Wood Dana of New York, a graduate of the College of Physicians and Surgeons, New York, in 1858, a member of the New York Academy of Medicine, and for many years on the staff of the New York Dispensary, died at his home on September 1, aged 87 years.

Dr. Charles Franklin Mohr of Providence, R. I., was assassinated on August 31 while in an automobile near that city. He was graduated from the College of Physicians and Surgeons, Baltimore, in 1891.

Dr. Green Vardiman Black, dean of the North-

western University Dental School, died August 31, on his farm near Virginia, Ill., at the age of 79 years.

Dr. A. WARD FOLLETT of Somerville, Mass., died on August 15 after a long illness. He was born in Royalton, Vt., January 27, 1858, and was graduated from the Dartmouth Medical School in 1881. He was for five years assistant superintendent of the Brother Hospital, Providence, R. I., then practised for two years in Cambridge, Mass., and removed to Somerville in 1888.

Dr. NATHANIEL W. LYNDE, who died in this city on September 3, was born in West Brookfield, Mass., in 1859, was graduated from Yale in 1882, and received his degree from the College of Physicians and Surgeons in 1885.

Dr. JOHN MILTON EDWARDS of Portland, Ore., died on August 26 at the age of 41 years. He was born in Mankato, Minn., and was graduated from the College of Physicians and Surgeons, Chicago, in 1899.

Dr. BENJAMIN H. CHEDISH of Omaha, Neb., died on August 18 in Kenosha, Wis. He was a graduate of the College of Physicians and Surgeons, Minneapolis, in 1903.

Dr. JAMES CHARLES FAHEY of Northampton, Mass., died August 24 at the age of 48 years. He was a graduate of the medical department of the University of Vermont in 1891 and had practised since then in Northampton, where he was for several years city physician.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HEALTH OF ARMY RECRUITS—CAUSES OF REJECTION—OBSTETRIC SECTION OF R. S. M.—POSITION OF FETUS IN UTERO—OBITUARY.

LONDON, August 20, 1915.

EVERYTHING connected with the war is occupying the attention of all parties. Recruiting is among the chief subjects of discussion just now, and its medical aspects are various. An interesting one is the relation to it of the sanitary and medical condition of schools. Drs. Finch and Hutt, who have both had experience in this department, have studied the problem, and in an interesting article point out some of the bearings of school medical work on the physique of the recruit. From the annual report of the health of the army they have compiled and contributed to the *Lancet* a table showing the rejections at inspection or within three months of enlistment. The figures give cause for reflection, as they show the total rejections amount to 22 per cent., and this they say does not necessarily imply that men offering themselves for enlistment are of inferior physique to the average population, for they have found when examining men of the territorial force as to their fitness for foreign service they had to reject nearly 20 per cent. This need not so much surprise us when we recall that other statistics would lead us to expect some such figure; *e.g.* those contained in the annual reports of medical officers of schools.

Of the causes of rejection a large group includes conditions associated with inferior physique, such as under-measurement (of chest), under-weight, and under-height, impaired constitution and debility, malformation of chest or spine, flat-foot. It is suggested that thorough medical supervision of school children would reduce these conditions, but obviously their effects only must be intended since defective formation is the affair of nature. Still, adequate feeding and physical training may accomplish something in a number of these defectives—add open air exercise and gymnastics, perseveringly carried out, and look for increase of chest measurement and other marks of improvement.

Another large group of defects is due to surgical diseases of the young affecting the teeth, the vision, the hearing, the joints. Hernia, too, is a very important matter, calling for early surgical treatment. Dental clinics have now been established in connection with many large schools, and will undoubtedly prevent much suffering at a later age. Defective sight naturally arrests the attention of teachers or, perhaps earlier, of parents, and should be referred to the medical attendant. Deafness is often present a long time before advice is sought, and then discharges from the ear will perhaps be found which are evidently of long standing. Medical inspection before school age would give better results, both curative and preventive. Open-air schools would have a beneficial influence, not only in this but in many ailments of the young, particularly catarrhal conditions of the naso-pharynx and enlarged tonsils and adenoids, which too often lead to middle-ear disease.

The Obstetrical Section of the Royal Society of Medicine has begun its session with the address of the president, Dr. W. S. A. Griffith, who took for his subject the causes which "determine the lie of the fetus in utero." This problem seems to have had a fascination for many observers from early times, and in the present day there are not wanting those who find it very attractive, among whom Dr. Griffith is an honored worker. In this address he gave an account of the systematic experimental investigation he has carried on so far, which he hopes will remove much speculation and many sources of error. He intends to continue his investigations and report results to the society. From early times statements were made which could only be guesses, as facts were wanting on which to base a conclusion. One of these guesses prevailed for ages, and even survives among the populace of various localities—that which asserts that the head lies upward until the seventh month, when a somersault is taken and the position of head downward remains to the end of the pregnancy. This notion might well have arisen in the movement of the fetus impressing the mother. William Hunter, correcting the error, wrote that neither reason nor instinct teaches the fetus "at a particular time any trick of a tumbler or rope-dancer." Thomas Raynalde, in his "Byrthe of Mankynde" (1545), described the position as head to the right angle of the matrice and legs across, adding "albeit there be that do describe the lyeing of the childe after another sort, but to be short they are lyars." In 1743 Onymos suggested the real position, and propounded the gravity theory as an explanation. This has continued to be widely accepted, although many authors have rejected it. Matthews Duncan supported it, Simpson opposed it. Dr. Griffith expressed his pleasure when studying the matter at finding many of Duncan's statements were correct. The position at the end of pregnancy is not disputed, but in the later middle months there was so much uncertainty that Dr. Griffith made use of every opportunity to determine the point, and was led to agree with Scanzoni, Veit, Dubois and others that

in the middle months the proportion of head-lowest in the living fetus increases from 50 per cent. before the sixth month steadily onward, while its mobility decreases as its size approximates to that of the womb, when such a great change as a revolution of the child could not well occur without some extraneous agent as exemplified in external version. We are fully justified, the lecturer declared, in concluding that if a fetus in the last three months lies head downward in the lower pole of the uterus and in the pelvic brim, it is very unlikely to alter under ordinary normal conditions. No other part is so adapted to the normal pelvis as the head.

The death is announced of Mr. Charles Holmes, F.R.C.S., at the great age of 99. At the age of 21 he qualified at the two royal colleges. He practiced for many years in Oxon and Bucks, and about 1875 retired to Emsworth. He was one of the first to receive the honorary fellowship of the Royal College of Surgeons.

Sir Peter Eads, M.D., consulting physician to the Norfolk and Norwich Hospital, has died in his 91st year. He took his medical degree in London in 1850, was knighted in 1885, was sheriff of Norwich in 1880-81, and had been mayor three times. He retired from practice in 1903, after a long career as eminent in the medical as in the political and social positions of Norfolk.

Brigade-Surgeon Lieut.-Col. H. Black Purves, late I. M. S., has died suddenly at Malvern. He joined the Bengal Army in 1865 and served at various stations, retiring in 1895.

Lieut.-Col. John Lees Hall, R.A.M.C., has died suddenly at the age of 60. He joined the army medical service in 1880 and became lieutenant-colonel in 1907. He was in the South African war as P. M. O. of a general hospital, and received the Queen's medal with three clasps. He retired in 1907, but for the last year has been employed temporarily with the R.A.M.C.

2. The Use of Digitalis in the Various Forms of Cardiac Arrhythmia. H. A. Christian.
3. The Relationship of the Abnormal Heart Beat in Prognosis. P. D. White.
4. The Treatment of Heart Disease. F. C. Shattuck.

1. Tuberculous Ileocolic Glands Simulating Appendicitis.—H. Gage points out that the predominant feature in the cases which he has observed as well as in most of the cases elsewhere reported, has been an attack of pain and tenderness localized in the right iliac region, of recent origin, accompanied by a slight rise of temperature and without demonstrable tumor; in only one of his cases was a small tumor believed to be present. Nausea was present in almost all, but vomiting occurred only in four.

2. Digitalis in Cardiac Arrhythmia.—H. A. Christian notes that digitalis slows the pulse rate and increases the work of the heart. It decreases the pulse deficit, *i.e.* the difference between apex beat and radial pulse. In cases of auricular fibrillation digitalis impedes conduction in the bundle of His; the ventricle consequently beats more slowly, there is more time for the ventricle to fill, and there is more time for the muscle to recover from fatigue. In some cases with auricular fibrillation in which edema is marked a much better diuresis is obtained by combining with the digitalis a diuretic drug, such as theocin. In another form of arrhythmia, namely, auricular flutter, digitalis usually produces a very striking effect. In pulsus alternans frequently digitalis produces good results. In true pulsus alternans the pulse is regular in rate, but every other beat is weaker than its predecessor. In such a case the pulse rate may be definitely slowed by digitalis. In the rapid, regular, decompensated heart digitalis, when it acts, appears to have a threefold effect. It slows the rate by increasing vagus inhibition and by increasing conduction time between auricle and ventricle, and it strengthens heart action by some direct action on the myocardium and coronary circulation. This type of case often seems definitely resistant to digitalis, and the patient may take large amounts before any effect can be detected. It is always well to remember in such cases to watch the patient carefully, for sometimes the digitalis action, which has been long delayed, develops with great rapidity into marked activity so that the patient, who shortly before has shown no digitalis effect, quickly develops toxic symptoms. In paroxysmal tachycardia there is very little evidence that digitalis produces any good effect.

3. The Abnormal Heart Beat and Prognosis.—P. D. White has observed that of all the disturbances of the rhythm of the heart beat, auricular fibrillation (absolute irregularity) and auricular flutter have the gravest prognosis, for not only are these conditions indices of myocardial damage but they themselves increase the difficulty of the circulation by their rapid driving of the heart. Sometimes, however, many years may elapse before the death of these patients. Of eighty-six cases of auricular fibrillation seen at the Massachusetts General Hospital 16 per cent. are known to have died within ten months of discovery. Premature beats and paroxysmal tachycardia are compatible with a long and active life, but their frequent association with cardiac damage should lead one to be a little cautious in prognosis. Permanent damage to the atrioventricular bundle of His or its branches is evidence of widespread damage to the myocardium. Hence the prognosis of a patient showing such a condition should be guarded. Defective contraction of the heart as shown by familiar symptoms and signs has a prognosis dependent on the number and degree of these symptoms and signs, plus a consideration of similar trouble in the past and of the way in which the heart responds to rest and digitalis. Of all the individual signs of abnormal contracting power of the heart pulsus alternans is one of the most important and consistent. Of eighty-three cases of alternation of the pulse seen at the Massachusetts General Hospital 31.3 per cent. are known to have died within ten months of discovery.

1. The Bone Graft Wedge.—F. H. Albee states that in many cases of hip dislocation the acetabulum is found to be too shallow and with a superior rim insufficient to retain the femoral head. To obviate this defect Hoffa in 1800 did his first successful operation, which consisted chiefly in deepening the acetabulum by scooping out the contained fat, articular cartilage, and bone to furnish an adequate concavity to receive and hold the head of the femur. By this method he was enabled to produce a

stable joint, but in many instances with little or no motion associated with pain, and in many others producing a stiff hip with a varying amount of shortening of the leg, depending upon the amount of excavation made in the superior portion of the acetabulum to receive the head of the femur. In cases in which motion seemed free shortly after the operation a later examination showed it to be slight, and at a still later period a proliferative arthritis which completely locked the joint frequently occurred. The author's method which has been performed successfully in a number of instances is said to obviate the above-mentioned disadvantages and produces a stable joint, with full and free motion and without pain or shortening. The most important feature is that it preserves the entire acetabulum and joint cartilage, thus guarding against any later joint change. It may be described as a bone wedge graft remodeling operation for paralytic and congenital dislocation of the hip. The important points of advantage which it is said to possess over the Hoffa open operation are: (1) it is an operation of less magnitude, producing less shock and mutilation of the anatomical joint structures; (2) there is a preservation of the synovial membrane and hyaline cartilage of the joint as well as of the ligamentum teres. The operation is performed without the disarticulation or extensive trauma of the head of the femur, a most important factor in avoiding shock and subsequent traumatic degenerative change in the joint. There is no shortening of the limb by the operation, as no portion of the existing articular structures is removed or scooped out as in the Hoffa operation. There is a restoration of joint stability and a reinforcing of the joint structures, and an actual addition to the joint anatomy by the insertion of these bone grafts to be described. The author's method minimizes any possibility of limited motion of the remodeled joint, or subsequent production of osteoarthritis to limit motion or produce painful motion.

2. **Pituitary Tumor.**—By W. M. Leszynsky. (See MEDICAL RECORD, July 24, 1915, page 172.)

10. **Acetonuria and Carbohydrate Starvation.**—S. H. Blodgett concludes that acetone in the urine may be caused experimentally by carbohydrate starvation, but not clinically, except to a very slight extent. Acetone alone or in conjunction with dietetic acid may, and in this unnamed condition frequently does, appear in the urine, often in enormous amounts, when there has been no carbohydrate starvation. Therefore the theory that a carbohydrate diet should be pushed in this condition appears to the author to be unfounded.

11. **Laryngeal Tuberculosis.**—A. S. Kaufman treats this condition as follows: In the early or catarrhal stage the patient is taught to spray the larynx with a mild alkaline solution in connection with the local application of mild astringents, followed by an oil spray. In regard to applications they should be made with the aid of a laryngeal mirror to guide the proper performance of this operation. Nodules and ulcerations call for surgical interference. The use of the punch in the former and the curette in the latter permits the medicaments which may be applied later to gain better results. Lactic acid, 25 to 50 per cent., and formaldehyde solution, 2 to 10 per cent., are efficient remedies when applied directly to the affected area, and not to the surrounding tissues. A drug recently used in this condition, and which has given very gratifying results, is scarlet red. Application of a 10 per cent. solution in oil causes a marked lessening of pain, and the ulcerations show a tendency to heal. Furthermore, it is nonirritating, and may be applied to the larynx without causing the patient discomfort by the use of the laryngeal mirror. For dysphagia, local anesthetics are indicated. The author has found that a 20-per-cent. mixture of orthoform and boric acid insufflated into the larynx gives relief for some time after its use.

3. A Two-Stage Operation for Carcinoma of the Rectum.—By D. F. Jones. (See MEDICAL RECORD, July 3, 1915, page 40.)

4. Multiple Benign Sarcoid of Skin.—J. Zeisler reviews the history of the conception of benign sarcoid and shows how the studies of it have rather complicated and multiplied the types. Darier in 1910 differentiated four types of sarcoid; (1) Boeck's type: the tuberus, papular and diffuse infiltrating form; (2) the Darier-Roussy type: subcutaneous sarcoid of the trunk, symmetrical and resembling tuberculosis; (3) "Sarcoides noueuses et nodulaires," resembling erythema induratum; (4) the Spiegler-Fendt type: round cell, nontuberculous tumors. Since 1910 there have been reported probably less than thirty cases. That many of the cases bear a greater or less degree of relationship to tuberculosis must be admitted, but Zeisler doubts whether one should unite the two. A somewhat different attitude may be justified regarding its relationship to syphilis as brought out by recent observations. The author mentions the remarkable capacity of syphilis for imitating other conditions, but it must be admitted that the positive Wassermann and even response to salvarsan do not necessarily establish a syphilitic origin for any lesion of the skin. Latent syphilis may coexist and have other diseases superimposed on it, and salvarsan itself often cures other cutaneous disorders than syphilis. It is therefore not improbable that some cases reported as sarcoid do not really belong to that type.

5. Chronic Intestinal Stasis.—By W. B. Russ. (See MEDICAL RECORD, July 3, 1915, page 39.)

6. Ileocolostomy and Colectomy for Arthritis Deformans.—By R. Smith. (See MEDICAL RECORD, June 26, 1915, page 1093.)

7. Lupus Erythematosus of the Mucous Membranes.—G. D. Culver states that the cutaneous lesions of lupus erythematosus are so deforming that they may monopolize the attention of the physician to the exclusion of those of the mucosa. He reports eleven cases showing the disorder in nineteen locations on the mucous membrane: inside of cheeks, five; gums, three; roof of mouth, one; lips, four; nose, two; and edges of eyelids, four. Nine of these eleven patients were females. Thomas Smith has also noticed this tendency for the disease to occur in women more than in men. One of the characteristics of lupus erythematosus of mucosa is its persistency. The lesions, when not acutely inflamed, are usually erosions covered with sodden epithelium and bordered by an irregular, noncharacteristic edge, which is but slightly raised. The patch may have a yellow coating or be leucoplasic, and, when the latter, is less char-

acteristic than that of lichen planus or syphilis, or from irritants. It is definitely patchy without papules, and though of long standing is less thickened than leucoplasic areas of syphilis or irritants. The mucous patches of syphilis have a dirtier appearance on the edges. The condition stubbornly resists treatment and often shows acute exacerbations definitely associated with disturbances of the general health, especially of the digestive tract. The gums are only exceptionally in good condition, and the history of easily bleeding gums is common. One of the most interesting conclusions reached by carefully observing all the phases of the lesions is that they are the result of a general disorder, and internal treatment and proper regimen are as necessary as local treatment.

8. **Plasma and Blood Volume in Pregnancy.**—J. R. Miller, N. M. Keith, and L. G. Rowntree state that from the beginning to the middle of the nineteenth century it was believed that the total volume of circulating blood increased during pregnancy, hence the theory of the plethora of pregnancy and the treatment of untoward symptoms by bleeding and cupping. Later it was shown that in the last months of pregnancy the red cells and albuminous contents of the blood decreased, while the white cells and water content increased, hence the theory of chlorosis of pregnancy was developed and increased diet replaced bleeding in the treatment. The authors review the literature of the subject and give the results of their own research, describing the technique and methods used. The determinations of plasma and blood volumes were made before or after labor, or both, in a series of thirteen women, and while the authors do not attempt to announce any far-reaching conclusions they point out the points of special interest and hold that their studies indicate that an absolute and a relative increase in the volumes of both plasma and blood exist late in pregnancy with a slow return to normal during the puerperium.

9. **Tuberculin Tests in Children of Colorado.**—By G. H. Cattermole. (See MEDICAL RECORD, July 3, 1915, page 36.)

10. **Pneumonia in Infants.**—By H. D. Chapin. (See MEDICAL RECORD, June 26, 1915, page 1092.)

11. **Etiology and Treatment of Ozena.**—H. Horn concludes from his investigations as follows: The *Coccobacillus fœtidus ozænæ* Perez, as isolated by Hofer, has answered all the bacteriological requirements necessary to establish its identity as the etiological factor in ozena. The isolation of this organism is attended with considerable difficulty. The production of agglutinating serum in rabbits is an exceedingly difficult task. The preparation of autogenous vaccines in every case is very difficult, if not impossible. At present mixed vaccines made from various strains of the Perez bacillus is the most practical method of treatment which is now available. It may be necessary to precede or combine with the treatment the vaccines made from the organisms which are usually present in combination with the Perez bacillus. It may be two or more types of ozena bacteriologically different but clinically identical.

12. **Prophylactic Application of Tetanus Antitoxin.**—H. E. Robertson describes the technique of his method as follows: Liquid antitoxin was poured on pads of sterile absorbent cotton in such amounts as to render the cotton uniformly moist but not wet enough to drip. These pads were then dried for twenty-four hours in a moderate heat (from 40 to 45° C.). A previously sterilized evaporating dish or earthenware mortar covered with a double layer of filter paper was found satisfactory for this purpose. Drying in vacuum did not appear to give any advantage. The dried antitoxin cotton became a stiffened mass resembling dried paper pulp. This was weighed and then divided into pieces which by weight would represent definite quantities of antitoxin; for example, if the entire mass contained twenty units of dried antitoxin, one twentieth by weight would represent about one unit. In wounds of mice, rats, or guinea-pigs, protection was given against the later injection of many times the minimum fatal dose of tetanus toxin or against the simultaneous inoculation of a garden earth which had been proved by numerous tests to produce tetanus in 100 per cent. of cases for unprotected mice, rats, or guinea-pigs. If the dry antitoxin pad was bound on a wound in which no fresh blood or serum was present, the absorption of antitoxin was greatly reduced and the protection therefore incomplete. If immediately previous to the application of the pad it was moistened in sterile saline, distilled water, sterile bouillon, or any clean fluid, absorption was rapid and protection entirely adequate. Pieces of this dried antitoxin cotton were used which were over six weeks old and were found to be perfectly efficient in the usual dosage. Amounts representing the dried product of from one to two and a half units (German standard) were employed, and rats weighing up to 200 grams were given full protection.

5. Calculi of the Prostate. R. L. Spittel.
6. The Causes and Treatment of Severe Pruritus Ani. P. Lockhart-Mummery.

1. **Neosalvarsan and the Blood Pressure.**—H. D. Rolleston finds that the average of both the systolic and diastolic blood pressures on the days after an intravenous injection is generally lower than before injection, the fall in the systolic being slightly more marked than in the diastolic pressure. This fall, however, is very probably not a direct result of the action of neosalvarsan, and, in part at least, may be due to rest in bed. The blood pressure seven hours after the intravenous injection of neosalvarsan is usually lower than it was before. The fall in the diastolic pressure is slightly less than that of the systolic pressure. The fall cannot be explained as due to fever. As compared with the blood pressure taken seven hours after the intravenous injection of neosalvarsan, the average of the blood pressure estimations on subsequent days is usually lower. This is more marked in the diastolic than in the systolic blood pressure. During the actual intravenous injection of neosalvarsan both the systolic and diastolic pressures are nearly always higher than on other occasions. This appears to be due to excitement. During the operation the pressures may vary considerably, the systolic blood pressure being more affected than the diastolic. The blood pressure before the first injection of neosalvarsan is nearly always higher than the blood pressure before the second injection of neosalvarsan, but here again mental excitement may be responsible. Finally, the general effect of intravenous injections of neosalvarsan is rather to lower, certainly not to increase, the arterial blood pressure.

3. **Artificial Pneumothorax in Treatment of Pulmonary Tuberculosis.**—C. H. Vrooman states that in order to obtain good results in this treatment it should be used in cases of recent origin. The moderately advanced case of recent onset, with the disease confined almost altogether to one side, is the type of case in which one should produce a pneumothorax at once.

Many of these progress rapidly, and at the end of six months must be classified as far advanced, so that by the use of artificial pneumothorax one has a most valuable adjunct to the usual methods of treatment. Incipient cases, with severe hemoptysis, should also be treated by pneumothorax at once. In so many of these there is such a rapid extension of the disease after hemoptysis that it is better to give the patients the benefit of this treatment. The author would not go so far as some and advocate that all incipient unilateral cases be treated, as the results with ordinary sanatorium treatment are good. His great complaint is, like that of all men in sanatorium work, that so few of these cases are sent for treatment. On the other hand, his experience does not encourage him to hope for much benefit from pneumothorax in the far advanced, long-standing cases. The far-advanced case which has recently become so should be distinguished from that in which the disease has been of some years' standing. A case of recent onset, which from physical signs one must classify as far advanced, but which from general condition is still moderately advanced, is eminently suited for pneumothorax, provided, of course, the disease is mostly unilateral. Artificial pneumothorax is, then, a valuable addition to the methods of treating tuberculosis, but unfortunately its application is restricted to not more than 5 per cent. of cases which have come under the author's observation.

5. **Calculi of the Prostate.**—R. L. Spittel reports two cases of calculi of the prostate, from one of which twelve faceted calculi were removed, and from the other forty-six seedling calculi. Prostatic calculi usually occur in middle life and old age. In the three cases that have so far come under the author's notice, the largest stones occurred in youths of 19 and 20, and small seed calculi in a man of 35. As to the origin of prostatic calculi it is known that, though lodged in the region of the prostate, they may have three modes of origin and formation: (1) They may be formed in the substance of the prostate gland itself. They have then as their basis the corpora amylacea with varying amounts of calcium phosphate and carbonate deposited round them, giving rise to stones varying in size from grains of sand to large calculi. (2) They may be formed in pouches, congenital or acquired, that communicate with the prostatic urethra, catching up deposits from the urine, and eventually forming stones that are more or less the moulds of the pockets that lodge them. (3) They may have their origin in the kidney or bladder, and become lodged in the prostatic urethra secondarily, where successive phosphatic deposits cause an increase in their size and mould them to the shape of the passage or diverticulum that gives them lodgment.

July 19, 1915.

Action on Asthma of Hypophysis Extract. — Riese gives credit to Weiss for introducing the use of this substance in the treatment of asthma (in 1912). The surprising character of the results obtained causes us to seek the rationale. The Weiss remedy has a private or semiprivate formula and is marketed as a proprietary. The author felt certain that its favorable action was due to hypophysis extract. The relief afforded was almost instantaneous. There were certain nervous collateral effects, most pronounced at the first injection, which spoke plainly for the presence of adrenalin—nervous excitation, tremor, and pallor. The author wrote Weiss to ask if adrenalin could be left out of the remedy, and the reply was that the entire formula was the result of long experience and could not be changed. The author then made a test of pure hypophysis extract in asthma, using it according to a system, and not only did he cure a case of chronic asthma in an elderly woman, but at the same time weaned her from the use of morphine to which she had become addicted. He used Weiss's remedy and hypophysis extract in the same subjects and could see no difference in their power over asthma, while the latter was free from unpleasant collateral activity. Weiss's remedy apparently contains two different hypophysis extracts plus adrenalin. But how can hypophysis extract relieve asthma if the latter is due to contraction of smooth muscle fibers? In theory it should produce spasm and not paresis. The spasmodic theory of asthma, however, is far from being demonstrable. The total volume of the lung tissue is increased in asthma, whereas according to the theory in question it should be diminished. The increased volume should be due to sudden paresis of the bronchial musculature. The sudden relief afforded by hypophysis extract would then be intelligible. According to our past notions the drug could act only through the sympathetic, and we know that adrenalin acts specifically on the latter and can be used to differentiate between sympathetic and autonomous fibers, the latter being derived from the cerebrospinal nerves. Adrenalin does indeed exert some power over asthma and the very rapid action of Weiss's formula is probably due to the adrenalin component. Hypophysical extract also acts in this manner. But Langley and some others have never accepted the teaching that the bronchioles are under control of the sympathetic. According to this school they are under the control of autonomous fibers derived from the vagus. The author, however, inclines to the sympathetic theory, and believes that asthma results from loss of tone in the smooth muscle of the bronchioles. We know that hypophysis extract cannot act on normal smooth muscle, but only when the latter has lost its tone; while adrenalin is a true sympatheticotropic substance. The two can therefore act as synergists in asthma. The action of atropin and the nitrites in relieving asthma is quite different, but has the same result; for these substances paralyze the antagonists of the sympathetic. Hence these remedies can also be used as synergists to the preceding and the asthmatic does indeed need all the synergists he can command. The favorable action of potassium iodide cannot be made to fit into the author's theory nor is it antagonistic. In all probability the injections of hypophysis extract in asthma in some way make good the disturbance of hormone balance which originally made possible the disease. The sympathetic fibers responsible for asthma may pass through the vagus. Persistent, systematic injections of hypophysic extract are able to cure asthma if they can restore to the musculature its lost tonicity.

Münchener medizinische Wochenschrift.

July 20, 1915.

Cryptogenic Fever.—Knoblauch and Quincke describe a peculiar epidemic or rather endemic of febrile affections in a large city hospital. Patients feel ill suddenly with fever of a pronounced remittent type. Every one of the eleven patients complained of right-sided pain over the lower ribs—a stitch, at times with tenderness on pressure. This showed a marked tendency to be reflected to the shoulder and scapula, of both the right and left sides. There were no finds on physical exploration and the entire picture was negative save for the pain and tenderness and elevated temperature along with such symptoms as accompanying fever in general, as depression and perspiration. There was some tendency to relapse. The condition passed off in a few days, save when relapses occurred, which seemed to

be the case especially in those patients who got up most promptly. The temperatures were of the degree called moderate (up to 104° F.). In regard to the nature of the cases pleurisy could straightway be excluded. Food poisoning was out of the question. The pains, radiated to the shoulder, suggested some affection of the liver, diaphragm, spinal roots, etc., but no evidence of such was forthcoming. Exposure was out of the question, as the cases occurred early in September. An insect bite visitation seemed a good tentative hypothesis and the author does not pursue his speculations further, save by systematic exclusion of fever due to catarrh or rheumatism. At the same time, from all that we know of the vagaries of "influenza," he cannot quite exclude such a diagnosis, even if that term is often a vague blanket expression for ocular endocarditis, sepsis, and many other febrile states.

The Ninhydrin Reaction in the Lumbar Punctates of Tuberculous Meningitis.—Nobel, an assistant to Professor von Pirquet, discusses the results of testing lumbar punctates with the ninhydrin method much used by Abderhalden in his serodiagnosis of pregnancy. The word "ninhydrin" is a contraction of a long-named chemical substance which is a delicate color reagent for the cleavage products of protein digestion. When ninhydrin is boiled with amino-acids a blue color is produced. The appearance of this reaction in lumbar punctates is of considerable value for the positive recognition of tuberculous meningitis. Its value appears in differential diagnosis. The test is very sensitive and the color reaction not marked. The content in the punctate of albumin has no significance. From ½ to 1 c.c. of punctate is boiled half a minute with 0.1 c.c. of a 1 per cent. solution of ninhydrin. Even if all albumin is removed from the punctate the presence of the amino-acids serves to give the reaction. The rationale of the test is bound up in the presence of proteolytic and peptolytic enzymes in the fluid obtained by lumbar puncture in cases of tuberculous meningitis. Then again, Nobel states, this presence of proteolytic and peptolytic ferments is associated with the greatly increased amount of albumin in the cerebrospinal fluid in this disease.

The Plague of Flies at the Front.—Kathariner in a letter to the Military Medical Supplement is not ashamed to go to the French for a practical solution of this problem. In a recent abstract in the MEDICAL RECORD the statement is in evidence that disinfectants are impracticable on such a large scale as would be demanded in fighting flies. But Roux of the Pasteur Institute (Paris) has devised a solution made up of 10 liters of water, 500 c.c. of heavy tarry oils and 2.5 kilos of iron sulphate, which, when poured over dung heaps destroys all odors and kills maggots. Better still, however, is 5 per cent. cresol, for its presence prevents the flies from blowing and also destroys all larval life when present. Plain 10 per cent. solutions of copperas or iron sulphate should be applied at once in stables to fresh dung and in the latrines of the trenches a little pure kresyl answers well. In trench life we have to fight certain known species of carrion and corpse flies (*calliphora, lucilia, sarcophaga*, etc.). From the trenches these insects reach the provisions and cuisine, for they are far better travelers than the house flies. Fresh meat may be sprinkled with tarry oils and left exposed with impunity, although cresol and formol have no deterrent effects on the flies. Iron sulphate is the best disinfectant to throw upon cadavers which cannot at once be buried. Either in powder or 10 to 20 per cent. solution it fairly tans a corpse and prevents decomposition. According to Roux, as quoted by Kathariner, cresol, tarry oils, and iron sulphate will between them do all the required work.

Deutsche medizinische Wochenschrift.

July 22, 1915.

The New Roentgen Tubes of Lilienfeld, Coolidge, and Zehnder.—Levy-Dorn first refers to the chief defect of the old tubes, to wit: the residuum of air in the nearly exhausted tubes which serves to transmit the current cannot be kept constant. Lilienfeld and Coolidge both aimed to produce an absolute vacuum in the tubes and replace the air particles with electrons given off by cathodes of incandescent metals or metallic oxides. Constancy can then be secured by regulating the especial incandescent circuit with a rheostat. Lilienfeld employed an aluminum cathode with concave mirror and an anticathode as in the usual tube, and an accessory cathode and special anode. The accessory cathode is rendered incandescent. Three circuits are required to operate the tube. First comes the heating circuit which heats the accessory cathode to incandescence. Next comes an ignition circuit by which the incandescent cathode is connected with its anode and has a low tension. Third is the ordinary high-tension current. The Coolidge tube has no ignition circuit, the regular and incandescent cathodes are fused together, and there is no secondary anode. Recently Koch has modified the Lilienfeld tube by leaving out the ignition apparatus and obtaining the same effect from a ramification of the regular inductor current. The result approximates more closely the structure of the Coolidge apparatus. Zehnder makes a complete departure in aiming to produce effects similar to those of the other apparatus. His tube is of brass with a glass or aluminum window. The anticathode is of copper coated with platinum, and the cathode is protected from the tube by a high-tension insulator. There is clearly no effort to produce a high-degree vacuum, and the inventor has not as yet applied for a patent. It may be possible to nullify the disadvantageous action of the gas particles in another way—by metallic occlusion.

Attempted Suicide with Tuberculin.—Janssen was summoned in the autumn of 1913 to see a patient who had been treated by him for several years with tuberculine for ordinary pulmonary tuberculosis. He found the patient very ill with high fever, tachycardia, and tachypnea. The original focus of disease showed no corresponding lighting up. The severe toxemia pointed to the existence of a suppurative focus. The treatment consisted of antipyretic measures and cardiac stimulants. In about three weeks' time the patient became normal with never the least sign of a toxigenic focus. Nothing could be learned from the woman patient by direct questioning. At last, however, she confessed that in a moment of despondency it had occurred to her that the tuberculin she was taking might be made to kill her. She got possession of a syringe and some tuberculin intended for external use and injected 2 c.c. at once. Although, as above stated, she was made very ill the focus in the being underwent notable improvement. Had she not received treatment, however, she would undoubtedly have perished from toxic cardiac failure. The old axiom that tuberculin used as a remedy should never produce a general reaction seems to be only partly true, for a highly poisonous dose brought prompt therapeutic benefit in this case.

The Pathology of Stuttering.—E. Fröschel distinguishes between tonic and clonic stuttering. The former is illustrated when the patient pronounces "p" as "pppp," "do" as "dodododo," "after" as "aaaafter," etc. Tonic stuttering cannot be easily described; in this the patient dwells for a long time upon the opening consonant of a word. The author attributes stuttering to an inhibition of the speech function. In some instances it may be regarded as an anxiety neurosis affecting speech.—*Arch. f. experim. und klin. Phonetik.*

Insurance Medicine.

Relative Death-Rates of Self-Declared Abstainers and Moderate Drinkers.—The *American Underwriter*, June, 1915, is devoted to a consideration of the relative death rates of abstainers and moderate drinkers from the actuaries' viewpoint. In an introduction to the discussion Edward Bunnell Phelps points out that facts and figures have not as yet clearly established these relative death rates, but that when that point has been reached the world will at least have the real measure of the physiological effect of the moderate use of alcohol on the ordinary man. As the mathematician and rate maker of the life insurance business, the final authority on death rates and premium rates, the actuary must be conceded precedence of all other judges in passing on the probable effects of alcohol on the lives of those life insurance policyholders who have acknowledged that they more or less frequently make use of it as a beverage.

Mr. R. M. Moore, actuary of the United Kingdom and General Provident Institution of London, read a paper at the Institute of Actuaries of London on November 30, 1903, in which he reviewed in great detail the tabulated mortality experience of that institution with the policyholders in the class of total abstainers to which it was restricted since its establishment in 1840 to 1849 and with that class and the class of non-abstainers in that year for the first time admitted to membership, from that time down to 1901.

These figures showed that the ratio of actual to expected mortality in the case of the male members of the Temperance Section for the period of comparison had been about 26 per cent. lower than that in the case of the male members in the general section. Mr. Moore's tabulations were accepted as convincing proof of the alleged wide measure of difference between the mortality rates of drinkers and non-drinkers in general. All the members, however, of the institution demurred from some of the implied conclusions of Mr. Moore's paper and many leading British actuaries promptly sounded warning against their too hasty acceptance.

At a meeting of the Insurance and Actuarial Society of Glasgow, on Febraury 1, 1909, Dr. E. Duncan discussed Mr. Moore's paper, and while conceding that there cannot be any doubt of the superiority of the male abstainer over the non-abstainer, the physiological limit of toleration of alcohol varies for different classes of people. For the robust adult of middle age at an outdoor occupation the daily amount of alcohol which can be consumed without any apparently deleterious effects averages 1½ ounces. For the average man of adult age at an indoor sedentary occupation 1 ounce of alcohol is the physiological limit. Duncan was not much impressed with the argument that alcohol was a virulent poison. Like many other wholesome substances it is undoubtedly poisonous in excessive quantity. In small doses, such as indicated above, it is not a poison to the ordinary man.

Mr. Emory McClintock, actuary of the Mutual Life Insurance Company of New York, in 1895 read a paper before the Actuarial Society of America. He concluded from a study of the statistics of the Mutual that the investigation did not show that those who drank only occasionally and not to intoxication, or those who drank habitually but lightly were, in any way, injured. It did not show that all of those who drank heavily must therefore die prematurely. It did show, however, that there was enough injury done to a sufficient number of individuals to make the death rate distinctly higher on the average. Again, it was admitted that death losses in excess among drinkers were not necessarily always due to drink. The coincidence between excessive drinking and lowered vitality might be partly due to bad risks taking to drink, as well as to good risks becoming bad because of drink. On the whole, however, the teetotal habit, not before but after middle age, must be counted as a favorable indication in judging of proposals for insurance from persons not known to be careful and moderate in the use of beverages.

Mr. John B. Langer, then actuary of the Prudential Insurance Company of America at the next meeting of the American Actuarial Society in October, 1895, discussed McClintock's paper and brought forward figures which seemed to show that there were lower death rates for rheumatism and Bright's disease with beer drinkers than with whiskey drinkers.

Recapitulating the evidence cited in the discussion which followed the reading of Moore's paper, Mr. A. Levine recalled the fact that the abstainers and non-abstainers departments of the New Zealand showed substantially similar mortality experiences with those related in Moore's paper. Mr. T. P. Whittaker said that many of the company's abstaining members were life-long abstainers, and sons of abstainers, and suggested that these facts largely accounted for the better experience of its temperance section, and supported the contention that abstinence did lead to longer life.

The president of the Institute, Mr. Hughes, sounded a warning note as to the uses which he clearly foresaw the figures in Mr. Moore's paper would be put, saying that enthusiastic temperance advocates would say that the favorable comparison between the two sections was due to abstinence from alcohol. The paper did not prove that.

According to the tabular showings of the Medico Actuarial Mortality Investigation of forty-three American and Canadian life companies in the years 1885-1909, the policyholders who, according to their own statements, had a daily drinking average of two or more ounces of alcohol had a mortality of 186 per cent. of the expected, as compared with a mortality of only 115 per cent. in the case of the men whose daily average was not supposed to exceed two glasses of beer or one glass of whiskey.

These figures for the 42,000 cases in all forty-three companies are at decided variance with those of the Northwestern Mutual Life's experience with all of its 166,694 policies written between 1886 and 1895 inclusive, brought down to 1900, the entire difference between the death rates of abstainers and all non-abstainers being but 11.15 per cent. and the death rate of drinkers of whiskey and other spirits being but 23 per cent. higher than that of presumably light drinkers.

Reviewing all the evidence the author of the paper in the *American Underwriter* thinks that the inevitable conclusion to which the abstract of actuarial experience and opinion leads is that the probable difference between the death rates of abstaining and non-abstaining life insurance policyholders is still utterly problematical, but that the tabulated experience of the North Western Mutual Life comes much closer to an approximation of the actual difference than have any other figures previously published.

Book Reviews.

NATURE AND NURTURE IN MENTAL DEVELOPMENT. By F. W. MOTT, M.D., F.R.S., F.R.C.P., Pathologist to the London County Asylums, Consulting Physician to Charing Cross Hospital and the Queen Alexandra Military Hospital, Formerly Fullerian Professor of Physiology, Royal Institution. With Diagrams. Price $1.50 net. New York: Paul B. Hoeber, 1915.

THIS little book relates especially to the respective parts played by environment and heredity in mental hygiene. The author states that he recognizes that he is dealing with a vast subject, embracing physiology, pathology, psychology, biology, medical science, hygiene, pedagogy and sociology. His chief endeavor, he says, has been to show that there is a correlation of mind and matter. He discusses in 151 pages the progress of sanitary science; mental hygiene from a physiological standpoint; the causes of mental deficiency; inborn potentiality of the mind and the social heritage; the raw material of character in relation to heredity; genius in relation to heredity; inheritance of pathological and individual characters, neuropathic and temperamental inheritance; sex in relation to character, crime, and insanity; racial inheritance and crime; the influence of nutrition and the influence of education, stimulus, sleep, pain, and pleasure, in mental development; the health of the mother and father; infant feeding; control of the emotions and inculcation of good habits, and sex and education. There is an appendix on the medical inspection of school children by one engaged in the work in Chester, England. There are 17 illustrations. The book is an amplification by the author of three former lectures. Among the more recent subjects of interest, the hormone theory is lightly touched upon, and some attention is paid to neuropathic inheritance in relation to crime and insanity. Some pedigree charts are introduced as examples of neuropathic inheritance. The various subjects are treated in a more or less sketchy way, but in an interesting style, understandable by the general reader.

THE ALLIGATOR AND ITS ALLIES. By ALBERT M. RIES, Ph.D., Professor of Zoology in West Virginia University; author of "An Introduction to Vertebrate Embryology." Small Octavo, pages XI-358, with 62 figures, and 28 plates. Muslin $2.50. G. P. Putnam's Sons, New York and London, 1915.

PROFESSOR Ries' treatise on the Alligator seems to be a most excellent monograph. The first chapter, "The Biology of the Crocodilia," is practically an introduction to the subject, and is interesting reading for any intelligent person. The following chapters are more technical, and deal with the skeleton, the muscles, the nervous system, the digestive system, the urogenital system, the respiratory system, and the vascular system. The treatment is concise and lucid.

Chapter X, "The Development of the Alligator," is based upon a paper of that title, published for the author by the Smithsonian Institution, and is much more complete than the other chapters. A severe critic might complain that this chapter overbalances the rest of the book. The whole book, however, is so readable and so beautifully illustrated, that one is not inclined to be captious.

PAINLESS CHILDBIRTH. A General Survey of All Painless Methods with Special Stress on Twilight Sleep and Its Extension to America. By MARGUERITE TRACY and MARY BOYD. With nineteen illustrations from photographs. Price, $1.50. New York: Frederick A. Stokes Company, 1915.

THIS book has been written for the lay reader, and like the numerous magazine articles upon the same subject, and indeed like many of the so-called popularized accounts of other medical topics, it seeks to disseminate doctrines that have not yet received the seal of general medical approval. There can be no question that the authors have written an interesting and eloquent account of the history and technique of the Freiburg method. But the scientific value of their book is not enhanced by the introduction of data that have no connection with obstetrical analgesia, data such as the hearty dinner received by the patient on the same day on which her baby has been born, "a dinner which may well happen to include two or three meats and vegetables; pork, perhaps, sausages, cabbages, cauliflower, brussels sprouts, desert." The unthinking non-medical reader may possibly gain an impression from the numerous photographs in this book that healthy and handsome children are the natural product of twilight sleep. The enthusiasm of the authors leads them to minimize one of the dangers of scopolamine-morphine analgesia, a danger now well recognized and admitted even by some of the former ardent advocates of the Freiburg method, namely, the danger of axphyxia in the child. Apparently too much stress is placed upon the influence of fear and pain in the parturient patient. One of the authors actually "personally lived through a sister's confinement!" Apart from its few shortcomings, which may be attributed to the authors' zeal, this book contains a full account of the history of analgesia in obstetrics, beginning with Simpson's introduction of chloroform in alleviating the pains of childbirth. The evolution of the Freiburg method and the respective contributions to it of Krönig and Gauss are described in detail. The experiences of those in America who have written upon this subject are quoted in full. The most valuable parts of this book to the medical reader are the appendices comprising translations of the original articles by the authors of the Freiburg method, as follows: "Painless Delivery in Dämmerschlat," by Krönig in the *Deutsche medizinische Wochenschrift*, 1908; "Births in Artificial Dämmerschlat," by Gauss in the *Archiv. für Gynäkologie*, 1906, and "Further Experiments in Dämmerschlat," by Gauss, in the Karlsruhe Address before the Conference of German Naturalists and Doctors. A useful bibliography on various pbases of analgesia in obstetrics is given at the end.

JOHN SHAW BILLINGS. A Memoir. By FIELDING H. GARRISON, M.D. Illustrated. Price $2.50. New York and London: G. P. Putnam's Sons, The Knickerbocker Press, 1915.

MOST medical men are, or should be, sufficiently informed as to the late Dr. Billings's scope of activities and the monuments to his fame—chiefly the Army Medical Museum, Index Catalogue of the Surgeon General's Library and Index Medicines, and also the part he played in the creation of the Johns Hopkins Hospital and New York Public Library, to say nothing of less known achievements. If this mere enumeration is not sufficient, Dr. Billings has been the subject of very many appreciations and eulogies, and biographical sketches of him have appeared for many years past, or as soon as the extent of his labors was understood. Dr. Garrison has given us a full biography, in which his subject is viewed from a number of angles. It comprises about 400 pages, and is above all criticism. Judged by the ordinary man, even by the ordinary distinguished man, Billings was a paradox as an American; since, with transcendent abilities, he preferred to serve his country in a comparatively humble capacity, during the best years of his life. His biographer ascribes this choice to simple loyalty to the government, and doubtless in Europe his indefatigable capacity for work, his executive ability, and power of organization would have led to governmental honors which have no counterpart with us. In his own country his abilities could have counted in various ways. He could have been one of our great surgeons, and considering the number of American physicians who have left medicine for high executive positions, and who have become capitalists and Congressmen, he should have found opportunities by scores to win fortune and power.

That he remained a shining example of one who in a relatively humble sphere performed titanic works does not at first sight harmonize with the descriptive appelatives "Viking," "Norman," and other terms which suggest sovereignty. We can only conclude that Billings looked much further into the future than most men, and, perhaps alone, saw and improved opportunities to erect certain foundations, which are well nigh imperishable, which can never be superseded, and which far outweigh anything he might have accomplished under more autocratic circumstances.

Not half enough has been said of the example set by Billings to workers in subordinate capacities who complain that they have no future, save in slow or fixed promotion. The services are of the type of institutions in the country in which exceptional ability cannot be recognized in a fitting manner. Billings was merely given the opportunity of doing what no one else would have welcomed or could have done; but throughout he remained a plain captain and major in the Army to the time of his retirement. Even thereafter he continued to work for a modest remuneration. He was in a way a survivor of that "antique world" when "duty sweat for service, not for meed."

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting Held at Rochester, Minn., June 9, 10, and 11, 1915.

(*Concluded from page 422.*)

Cavernous Angioma of the Spleen.—Dr. CHARLES N. DOWD of New York said that angiomas of the spleen were very uncommon; some of them had ruptured and had been reported as blood cysts, others had undergone such changes as to be classified under sarcoma. A tabulation of 13 cases of cavernous angiomas was given. In six of these cases other organs besides the spleen were involved in the growth, especially the liver. The author reported one case in a woman of 37, who for six months had noticed a splenic tumor which had extended into the epigastrium across the median line. Splenectomy was done. At the operation angiomatous spots were noticed in the liver. The patient recovered from the splenectomy but thirteen days later suffered from liver hemorrhage similar to that which had occurred in the spleen. The liver enlarged greatly and the patient died six weeks later.

Abscess of the Spleen.—Dr. ARTHUR W. ELTING of Albany, N. Y., said that abscess of the spleen had been known to follow a great variety of acute infectious diseases, as well as some of a more chronic nature, especially those associated with a splenic tumor. In many cases the original portal of entry for the infecting microorganisms had not been demonstrable. Many cases of left-sided subphrenic abscess had undoubtedly been abscesses of the spleen. Abscess of the spleen always resulted from contiguous or metastatic infection, the latter being by far the more frequent. The bacteriology of the process had been very varied. Almost every variety of pyogenic organism had been cultivated from splenic abscess, while in some instances the pus has been sterile. Most abscesses of the spleen were embolic or thrombotic in origin, and developed in infected infarcts. Typhoid fever was the most common single cause of abscess of the spleen, with malaria next as an etiological factor. The prognosis was better in post-typhoid spleen abscess than in any other variety. In many cases of abscess of the spleen, there was a sequestration of spleen tissue, the sequestra varying in size from minute bits to the entire spleen. The symptoms of abscess of the spleen were suggestive rather than distinctive. Enlargement of the spleen, pain in the splenic area, and inflammatory involvement of the diaphragm or pleura at the base of the left lung, were the most important symptoms. Chills, fever, nausea, vomiting, and diarrhea often occurred and a marked leucocytosis was a frequent accompaniment. Radiography was of importance in making a diagnosis, but the most essential diagnostic measure was exploratory aspiration of the affected area. The treatment was always surgical and should be splenotomy or splenectomy, usually the former. The operative procedure would be through one of three routes: (1) the transpleural, (2) the abdominal, and (3) the retroperitoneal. The prognosis of abscess of the spleen, recognized reasonably early and adequately treated surgically, was relatively good. In the case reported by the writer, the onset was sudden, with pain in the upper left abdominal quadrant, fever, and prostration, with some enlargement of the spleen and a pronounced leucocytosis; no definite portal of entry for the infection was found. This condition continued for 20 days, when the temperature became normal and remained so for 6 days, with marked improvement in every way. The temperature again became elevated and the signs all pointed to the splenic area. Numerous Widal reactions and blood cultures were negative, but a high leucocytosis persisted. Repeated exploratory aspirations, as well as radiographs, produced negative results in the early stages. Finally the radiograph and the aspirating needle located pus in the region of the spleen, and transpleural drainage was done and a sequestrating abscess of the spleen disclosed. Cultures from the pus showed pneumococci. The patient improved for a time, but finally died, with all the evidences of a suppurating portal phlebitis.

Banti's Symptom Complex.—Dr. JOHN BAPST BLAKE of Boston, Mass., read this paper in which he said that splenectomy in splenic anemia, or Banti's symptom complex should be recommended under the following conditions: (1) In adults, when the diagnosis was agreed upon by a good physician and a competent surgeon. (2) When the condition of the patient was sufficiently good to withstand what might be a very serious operation; or when a poor condition could be sufficiently improved by one or more previous transfusions. (3) In children, only after a very thorough trial of all possible medical methods of treatment including fresh air, sunshine, careful nursing, liberal and appropriate diet, as well as the judicious exhibition of drugs. In a large majority of cases, a high white count or a considerable recurring or continuous fever were contraindications. In children also the agreement of physician and surgeon was an essential preoperative requirement. Splenic anemia was distinctly a borderline condition. In adults, most physicians of wide experience agreed that it was cured only by operation, and that it was by this means permanently cured. In adults, therefore, it was not necessary to wait (except for transfusion) once the diagnosis was established. Banti's symptom complex was in most cases a slowly progressing condition, often with periods of considerable temporary improvement; in a minority of instances the disease progressed rapidly; in practically all cases it terminated fatally. Unfortunately, neither the public, nor indeed the profession taken as a whole, was convinced of the importance of the early operative attack.

Splenectomy for Hemolytic Icterus.—Drs. CHARLES A. ELLIOTT and ALLEN B. KANAVEL of Chicago presented this communication. They first reported a case of splenectomy in a patient suffering from hemolytic jaundice of the familial type. The patient upon whom the splenectomy was done was a man of 54 years who had suffered all his life from the acholuric crises of malaise, headache, tenderness over the spleen, and slight fever, and on examination presented a large spleen, a marked anemia, and a fragility of red blood-cells at 0.54 per cent. Following the operation the patient had an uneventful recovery and reported himself two months later as having absolutely no icteric tinge, the urine was clear of urobilin, the red blood-cell count was normal, and in every way he could be said to be cured. The authors drew attention to the fragility test of Chauffard and Widal and discussed the method of arriving at their results. The fragility test in the various hemolytic cases examined varied from 0.46 to 0.54 per cent. at the beginning of the breaking down of the blood. The results of investigation as to the fragility in the splenic artery and splenic vein of dogs showed that the artery in the majority of cases presented a higher fragility of its cells. In discussing the pathogenesis, the authors leant to the assumption of Eppinger, who explained the destruction under the title of "hypersplenism." The results of the study of cases of splenectomy for this condition showed that practically all of the cases made complete recoveries after operation. There were two primary deaths. The average weight of the spleens removed was 1,000 grams. Liver crises due to the passage of an excess of thickened bile or of gallstones were present in six cases operated upon, and in four of these gallstones were found. The pathology showed an absence of connective-tissue proliferation with a constant infiltration of the pulp of the spleen with the blood-cells. There was no connective tissue proliferation and no increase in the size of the liver. The authors recommended splenectomy in these cases and believed that the operation should be performed early, particularly in the younger individuals where it would not seem advisable to wait for marked disability and the development of a large splenic tumor. On the other hand they drew attention to the fact that where there was an absence of disability it was inadvisable to operate in these patients as they might grow to old age without any serious complications.

Dr. HOWARD LILIENTHAL of New York referred briefly to seven cases of splenectomy, two for Banti's disease, one for Banti's disease with traumatic rupture, one unrecognized pseudoleukemic spleen, one case of pernicious anemia, one case of traumatic rupture of the spleen and one case of passive congestion of the spleen. Of these five patients recovered.

Dr. CHARLES L. GIBSON of New York mentioned five cases of traumatic rupture of the spleen, two cases of splenectomy for acholuric (hematogenous) jaundice, two cases of splenectomy for Banti's disease, one case of splenectomy for von Jaksch's anemia, one case of splenectomy for ecchinococcus cyst of the spleen, and one case of attempted splenectomy in splenomyelogenous leukemia. Three of the traumatic cases, both cases of acholuric jaundice, one case of Banti's disease, and the case of von Jaksch's anemia ended in recovery,

as did also the case of ecchinococcus cyst. In the case of splenomyelogenous leukemia splenectomy was impossible, due to the enormous size of the spleen, and the patient died on the tenth day following operation. In this case the operative interference was done at the earnest request of the patient.

Dr. W. A. Downes of New York reported eleven cases of splenectomy performed during the past three years with five deaths. In this series was included one case of spontaneous rupture of the spleen in typhoid fever and this was supposed to be the only one on record which had terminated favorably.

Dr. K. A. J. Mackenzie of Portland, Oregon, cited a case of splenomegaly associated with polycythemia and suggested that such a condition might well deserve more serious attention from the surgeon.

Dr. E. H. Pool of New York referred to two cases of von Jaksch's anemia occurring in his practice during the past year. He advocated in this condition that if persistent and careful medical treatment did not produce satisfactory results, removal of the spleen should be considered; if the anemia is marked, he stated that a preliminary transfusion should always be done.

Dr. Charles H. Peck of New York reported a case somewhat similar to that mentioned by Dr. Mackenzie, a polycythemia associated with splenomegaly; this condition was accidentally discovered in a patent admitted for coccygodynia. There was a hemoglobin of 140 per cent. and an erythrocytosis of 8,000,000, with a much enlarged spleen. He found in the literature that such a case was considered unsuitable for splenectomy and was to be classed as lenkemias. He also referred to a case of hemorrhagic acholuric jaundice, on which he did a splenectomy three years ago with a good recovery.

Dr. Fred T. Murphy of St. Louis mentioned a typical case of the Gaucher type in a child of six, in which he had recently operated.

Dr. Arpad G. Gerster of New York discussed the technique of splenectomy. He also reported a hitherto unpublished case of abscess of the spleen. This patient was admitted as an emergency case to the hospital, with high fever and symptoms of perforation; previous history unknown. Physical examination disclosed an effusion in the left pleural cavity, and a tumor occupying the left subphrenic space. A diagnosis of an acute suppurative process was made (the spleen as such could not be made out) and a puncture was made from behind. This proved a very satisfactory procedure, yielding seropus, and he then entered by the posterior route which gave an exceedingly easy access to the spleen. A large abscess was evacuated in which there were stomach contents as well as pus; there was a perforation of the stomach into the abscess; whether this perforation had led to the development of the abscess, or whether the latter had pointed into the stomach, could not be determined. A jejunostomy was immediately made, but the high fever continued and the patient died. Dr. Gerster recommended a posterior incision under suitable circumstances.

Dr. Willy Meyer of New York reported three cases of splenectomy; the first, done about twenty years ago, was a case of leukemia, which was before the time that this condition was recognized as a contraindication to splenectomy; the patient ded from secondary oozing. The second case was one of sarcoma of the spleen, evidently a primary tumor, as the liver was not involved; the patient died six months later from metastasis. The last case was one of splenomegaly in a man over forty years of age with recovery. Dr. Meyer stated that all of these operations had been done with the T-incision, first in the median line, then with another incision at right angles, meeting the costal margin outside. He emphasized the necessity of impressing upon the medical man the fact that splenomegaly is a surgical disease and that these cases are curable by operation.

Dr. Francis T. Stewart of Philadelphia called attention to a case resembling that detailed by Dr. Gerster, in which he was so certain of the diagnosis of abscess of the spleen that he made no preliminary puncture, but performed a splenectomy only to find the condition to be one of leukemia; the patient died.

Dr. William J. Mayo of Rochester, Minn., alluded to the apparent size of the spleen, and stated that few surgeons recognized enlargement of the spleen unless able actually to feel it beyond the costal margin. Jaundice, which formerly was thought always to mean something in connection with the biliary tract, gall-bladder, or pancreas, was now known to be due also to a diseased spleen and its effect on the red blood cells. He mentioned three cases of so-called leukemia, showing, however, no increase of white cells, in which splenectomy was followed by recovery. He insisted that true leukemia was a non-surgical condition, but believed that every chronically enlarged spleen should have a reason for non-operative interference.

Partial Occlusion in the Treatment of Aneurysm.—Mr. Edward Martin of Philadelphia reported three cases of arteriovenous aneurysm involving the internal carotid and the cavernous sinus; one operated upon by Dr. Deaver, the common carotid of one side being ligated, and two operated on by Dr. Martin under local anesthesia; in each case a unilateral carotid ligation had been made supplemented by ligation of a group of orbital veins for the purpose of promoting local thrombosis. All three patients were promptly and permanently cured. Dr. Martin urged the combined carotid and orbital ligation supplemented by serum injections, starvation diet, limitation of liquids, daily and non-straining movements of the bowels, and absolute rest in bed for two or three weeks, making this endurable to the patient by the judicious use of anodynes. Although the complete ligation of the carotids alone gave about 60 per cent. of cures, he pointed out that even in pulsating ophthalmos the immediate and remote mortality and subsequent crippling from brain lesions were sufficiently frequent (20 per cent.) to act as deterrent factors against this procedure. The partial and temporary carotid occlusions he obtained by chromic catgut in one instance, by tendon in the other, and he advocated the use of a fascial strip taken from the patient. He noted that all non-absorbable occluding media exhibited a tendency to discharge into the lumina of vessels about which they were placed.

Dr. Arthur Dean Bevan of Chicago in connection with ligation of the carotids for arteriovenous aneurysm following skull fracture, suggested first the ligation of the common carotid; if this proved inefficient, then the ligation of the external carotid, just above the superior thyroid, which would carry with it a certain amount of circulation that would tide over the brain on that side. If this also failed the final step should be the ligation of the internal carotid.

Dr. Howard Lilienthal of New York reported an unusual case of mastoiditis which after operation developed a left pulsating exophthalmos with divergent squint, with enlarged vessels in the orbit above the lid, and with tinnitus. He ligated both common carotids within ten days of each other. After a short period the tinnitus recurred. The skull was then opened by the Hartley-Krause osteoplastic method as he believed there was an arteriovenous aneurysm of the cavernous sinus; no area of pulsation could be found. The patient recovered from the operation but was not well, desired further treatment, and a ligation of an enlarged artery in the neck was performed. Death occurred a few hours later from recurring hemorrhage, due to the slipping of the ligature. An interesting point in this case was the ligation of the common carotids within ten days of each other without serious cerebral symptoms.

Dr. Ellsworth Eliot, Jr., of New York recommended partial occlusion of arteries as a valuable method of treatment in aneurysms which were inaccessible and considered it preferable to arterial ligation when such a measure threatened the viability of vital centers. In aneurysms of the extremities however, he preferred excision of the aneurysmal sac if such could be easily reached, when the anastomotic circulation was sufficiently abundant to preclude the danger of gangrene.

Dr. C. A. Hamann of Cleveland reported a case of traumatic arteriovenous aneurysm involving the internal carotid and lateral sinus, successfully treated by ligation of the common carotid.

Dr. A. W. Elting of Albany, N. Y., referred to two cases of pulsating exophthalmos, in one of which there was a definite history of trauma but in the other no such history. The first case was cured by ligation of the common carotid; in the second case ligation of the internal carotid was followed for a day or two by improvement, with however, a few days later, recurrence of all the original symptoms; after a few weeks there was entire disappearance of all symptoms with permanent cure.

End Results of a Series of 300 Operative Cases of Disease of the Biliary Tract.—Dr. John J. Buchanan of Pittsburgh, Pa., read this paper. He was able to trace all but 18 of his cases—giving 94 per cent. of known results. The primary mortality was 4.66 per cent.; 32 per cent. of the cases were acute; 95 per cent. were

drained and only 5 per cent. excised; prompt and permanent recovery ensued in 81.7 per cent. of the drained cases and an additional 5 per cent. were later cured by nature or by surgical means. The writer concluded that, while cholecystotomy was not a perfectly satisfactory operation, it was perhaps more satisfactory than cholecystectomy for surgeons of ordinary skill. As a surgeon's experience and skill increased he was more disposed to practise excision. There was a field for both operations, and that surgeon would have most success who not only considered the condition of the patient, but estimated justly his own capabilities.

Papillomas of the Gall-Bladder.—Dr. CHARLES H. MAYO of Rochester, Minn., said that few operations on the gall-bladder were of recent development. The not infrequent discovery of an apparently healthy gall-bladder in operations for gallstones caused general exploration to become a routine procedure. Thick walled gall-bladders without stones were next drained or removed. Later came the appreciation that a diseased mucosa could exist in a gall-bladder of healthy external appearance. If inflammation was from bacterial infection the lymphatics draining the diseased area was enlarged and soft in acute processes and harder in chronic processes. If there were no gallstones and little change in the appearance of the gall-bladder the lymphatic glands on the cystic duct and along the hepatic and common ducts should be palpated. If they were found to be swollen without other adequate cause the gall-bladder should be removed. If the glands were not swollen and no stones were found, then search must be made for other source of symptoms. Rosenow's theory of the cause of this inflammation seemed plausible. Bacterial invasion of the wall of the gall-bladder might cause changes in its circulation with edema, infiltration, exudation, swelling of the lymphatic glands, and local necrosis of the mucous membrane. Papillomas of the gall-bladder occurred in the same manner but instead of a primary destructive effect there occurred locally an overgrowth which might later become necrotic. Papillomas were found in 107 of the 2,538 cases of cholecystectomy in the Mayo Clinic from Jan. 1, 1907, to June 1, 1915. From a surgical standpoint, it was important to note that the papillomas of the gall-bladder were not cured by temporary drainage but that cholecystectomy should be performed.

Dr. S. J. MIXTER of Boston, Mass., strongly advocated the performance of cholecystectomy in preference to cholecystostomy. He was among the first to advocate the more radical measure, which he had practised for many years, and he was convinced that the advantages of this method were not to be questioned.

Dr. GEORGE W. CRILE of Cleveland said that his end-results in cholecystectomy had not been uniformly favorable and cited two instances, one in his own practice and one in the practice of a colleague, where very small stones later formed in a tiny bit of mucous membrane left at the bottom of the gall-bladder, producing a diminutive cholecystitis with blocking of the cystic duct. Both cases were finally operated upon a second time by the speaker with much difficulty.

Dr. JOSEPH C. BLOODGOOD of Baltimore stated that in the last two years at the Johns Hopkins Hospital he had studied a group of a thousand cases of operation upon the gall-bladder. Cholecystostomy was the usual procedure; in these cases there were 60 cases of cancer, in only two of which was the disease removable. He suggested that the future treatment of gall-bladder conditions be instituted early in the disease, with the hope that interference would take place before the development of cancer. Cholecystectomy was a protection against the development of cancer. He stated that in the series mentioned there had developed no cases of cancer of the gall-bladder where drainage was instituted in which at the time of operation careful examination showed no evidence of malignant disease.

Dr. W. D. HAGGARD of Nashville reported a case of cholecystostomy in which the patient developed carcinoma within a year.

Dr. WILLY MEYER of New York reported another case in which cholecystostomy was followed by the development of cancer at the site of the drainage tube eight months later. A second operation was refused and the patient died.

Dr. ARCHIBALD MACLAREN of St. Paul reported a case of cholecystectomy followed in eight months by cancer of the stump of the gall-bladder.

Dr. J. J. BUCHANAN of Pittsburgh stated that he had been able to follow ninety-four per cent. of his cases, and in none of these had carcinoma developed.

Resection of the Cardia for Carcinoma.—Dr. WILLY MEYER of New York read this paper. He stated that he offered his report with some hesitation, inasmuch as the two patients upon whose operations it was based did not pull through. However, he was so fully convinced not only of the feasibility of the work, but of the possibility of a more frequent recovery from operation than had hitherto been observed, that he felt impelled to write the paper. He first referred to five resections of the cardia followed by an operative recovery. They were the cases of Voelcker, Kümmel, Sauerbruch, Zaaijer, and Ach, each done by a different method, which he illustrated by lantern slides. He then proceeded to tell of his own experience with two operations done in the course of the winter, one at the Post-Graduate, the other at the German Hospital. He emphasized the necessity of doing the operation in stages, the first to represent gastrostomy with careful palpation of the pathologic conditions at and around the cardia; the second to consist in attacking the tumor from the abdominal cavity, if the healthy portion of the esophagus above the tumor could be reached from below. He strongly advised following the method of Ach, according to which the proximal stump was extracted from the posterior mediastinum through an esophagotomy wound at the neck and transposed downward under the skin of the chest. Dr. Meyer carried out the extraction method in both instances, but was forced each time by adverse conditions found to add a thoracotomy at the same sitting. However, abdominal section plus thoracotomy plus esophagotomy evidently was too much for these reduced patients to stand at one time. In his second case the intratracheal insufflation did not work satisfactorily and was seemingly the principal cause of the fatal issue. In both his cases the work had to be done in the presence of and with preservation of a previously established gastric fistula, a point which did not have to be considered by the operators whose cases were reported. Dr. Meyer stated that Ach carried out the extraction method by means of a wire loop, introduced to the stump of the esophagus, which loop was then pierced with needle and thread. The latter was knotted and served to withdraw the esophagus from the posterior mediastinum. However, this kind of procedure added an element of sepsis and Dr. Meyer therefore had constructed a new esophageal extractor which obviated this drawback. He tested it in the dog with entire satisfaction and stated that he saw no reason why it should not work equally well in the human subject. All the steps of the resection of the cardia as witnessed in his two cases, also of the new instrument and of Ach's extraction method were illustrated by lantern slides.

Dr. ARTHUR DEAN BEVAN of Chicago said that thoracic surgery, being accompanied by enormous risks and requiring expert and experienced workers with perfect technique, should be turned over to specialists in this field, in order that the pioneer work might be carried on only by skillful men interested in the perfection of this field of surgery.

Dr. LEONARD F. FREEMAN of Denver recorded an operation performed seven years ago for carcinoma of the lower end of the esophagus. He gave a detailed description of the method of procedure. The patient rallied well from the operative shock, but unfortunately died some four days later of pneumonia. There was apparently no leakage from the site of the gastro-esophageal anastomosis.

Non-Calculous Obstruction of the Upper Ureter.—Dr. CHARLES H. PECK of New York presented a report of fourteen cases of upper ureteral obstruction to illustrate the principle of "splinting the ureter" as a part of the operative procedure, for the purpose of preventing recurrence of obstructions from fresh kinks, adhesions, or angulations, while the kidney and ureter were becoming fixed in their new position. A ureteral catheter or probe was passed through a stab wound in the kidney cortex to the bladder and secured to the skin by adhesive straps. It was removed after three or four days. The fourteen cases included examples of valvular obstruction at the pelvic ureteral junction with hydronephrosis and other types of non-calculous obstruction. None of the cases had had recurrence of symptoms or had required secondary operation. Plastic resection of the kidney pelvis, nephropexy, etc., were done according to indications in each case before the ureteral catheter was placed.

Fistulous Communication between Stomach and Colon Following Gastroenterostomy.—Dr. C. A. HAMANN of Cleveland presented this communication. A gastro-

jejunal ulcer, following gastroenterostomy, might result, he said, in a fistulous communication between the stomach and transverse colon. There was some thirteen such cases upon record. The leading symptoms of such a condition was fecal odor of the gastric eructations and perhaps fecal vomiting, diarrhea (sometimes lienteric in character), and loss of weight. As there was usually also an opening into the jejunum, the term "gastro-jejuno-colic fistula" was an appropriate one. The author reported a case in which this condition ensued after gastroenterostomy and partial gastrectomy. The patient recovered, after separation of the stomach, jejunum, and colon from one another, closure of the openings in the stomach and jejunum, resection of four inches of the colon and the making of a new gastroenterostomy.

AMERICAN PEDIATRIC SOCIETY.

Twenty-seventh Annual Meeting, Held at Lakewood, N. J., May 24, 25 and 26, 1915.

THE PRESIDENT, DR. GEORGE N. ACKER OF WASHINGTON, D. C., IN THE CHAIR.

Monday, May 24—First Day.

President's Address.—Dr. GEORGE N. ACKER delivered this address in which he spoke of the importance of Child Welfare work. He said that this subject had found national expression in the establishment of the Children's Bureau of the Department of Labor. This Bureau, under the guidance of its director, had done creditable work at Johnstown, Pa., the results of which had been embodied in the first report of the Children's Bureau in its study of infant mortality in the United States. According to this report the death rate among children was in direct proportion to the earning capacity of their fathers. The infant death rate was five times as high in a poor unsanitary section of the city as in a better residential district. In families where the earning capacity of the father was $10 per week, the infant mortality was 256 per 1,000 births; in those in which it was in excess of $25 the mortality was 84 per 1,000 births. This report seemed to show the importance of breast feeding for at least three months. A high infant mortality was found to be coincident with neglected streets, unsanitary housing, taking boarders in the home or working outside the home on the part of the mother. This Bureau was trying to find the conditions of life which were most favorable to the American baby in every respect. Since the problem was an economical one it became the duty of the State to provide the necessities for healthful living if the parents were unable to do so. Dr. Acker spoke of the advantages that accrued from playgrounds, school lunches and the classes for teaching girl pupils the care of infants. He expressed the opinion that the effects of the European war would be shown in a physically and mentally weakened offspring attended by a correspondingly high infant mortality and that this country would not escape this result altogether. That much could be done to lessen this evil was shown by Professor A. Pinard who stated that the infant mortality in Paris was 21 per cent. less during the first six months of the war than during the same period of the preceding year, and that the maternal mortality had decreaed proportionately during this time. These results were attributed to the measures taken by the maternal and infant aid societies organized at the beginning of the war. The danger of contact infection with tuberculosis had been too much neglected and the mistake had been made of laying too much emphasis on the destruction of infectious material at the expense of building up individual resistance by good food and proper hygiene. The infant constantly exposed to tuberculosis infection was as much entitled to protection as authority would give it were the disease smallpox or diphtheria. Dr. Acker suggested that a reform should be brought about in the chaotic condition of the principles of infant feeding, and also that it might be wise to enlarge the membership of the Society. This latter might be done by providing an associate membership from which men could be advanced to full membership on a basis of merit.

Cubic-Air Space for Institutional Bottle-Fed Infants.—Dr. THOMAS S. SOUTHWORTH of New York read this paper. He pointed out the shortcomings of the New York State law with reference to stating that while ventilation was a nominal requirement, such ventilation was neither defined nor enforced. There was no apparent evidence that the laws and rules were based on competent pediatric authority. The writer had sent out a questionaire to each member of this society with the hope of securing some definite data of value and authority on this subject, the inquiry being restricted as far as possible to bottle-fed infants under one year of age unaccompanied by their mothers. Dr. Southworth reviewed the questions which had been asked and analyzed the answers from which he concluded as follows: (1) The majority of hospitals and institutional wards for infants from which reports were received, provided 1,000 cubic feet air space and upward for each inmate, and only five reported 600 cubic feet or less (the legal requirement). (2) Even with 1,000 cubic feet of air space free ventilation was considered highly important, and as the space decreased such free ventilation became more and more imperative. No allowance of cubic air space was at present made for the attendants in the wards. (3) Reduced cubic air space meant less square feet of floor space and less separation between cribs, with proportionately increased opportunity for the spread of cross infections. Adequate separation of the beds was only attainable with large cubic air space. (4) On account of their handicaps, bottle-fed babies were likely to require more space than nursing infants. (5) Bottle-fed infants required as much air space as sick or "medical" or "surgical" cases among infants. (6) The majority of pediatrists believed that infants should have as much cubic air space as adults, if not more and this was especially true of bottle-fed infants, because they were more susceptible to infection, suffered in their confinement and did badly in all save the best equipped institutions. (7) Limited cubic air space involving limited floor space, was an important contributory factor in the high mortality of artificially fed infants, and such crowding in limited space was very commonly the concomitant, if not itself the cause of faulty hygiene, insufficient care and inadequate nursing. (8) Even with a liberal allowance of cubic air space free and abundant ventilation was of equal importance; in addition, provision for roof gardens, porches, and sunparlors was advisable, if not imperative. (9) The mere presence of windows did not of itself constitute ventilation, but their proper use must be provided for. (10) A low minimum of cubic air space established by law, without definition of what constituted efficient ventilation and without enforcement, might be more harmful than beneficial, and might constitute a virtual license to overcrowd in ill-ventilated wards. (11) The example of the more progressive hospitals and institutions which provided the large amounts of air space per infant, together with free ventilation, was to a considerable extent nullified by state and local regulations, licensing for the less progressive, the employment of a minimum air space for a class of infants among whom there was admittedly an unduly high death rate.

Dr. L. EMMETT HOLT of New York pointed out that the problem was a difficult one for pediatrists since so much depended on the co-operation of hospital authorities. He also brought up the question to whether children having hospital care did better in separate institutions or in a special department of a general hospital. In some ways children were better off in a special institution since they required a special kind of care and in children's institutions a special construction was desirable, while in a large general hospital there were certain advantages, training schools for nurses, opportunities for consultation with physicians in other special departments and opportunities for the training of internes that would give them experience in dealing with children's diseases. A given number of children needed from two to three times as many nurses as would be required for the same number of adults.

Dr. ROWLAND G. FREEMAN of New York said that in the matter of cubic air space what the child needed was free moving air. Out-doors was better than in. Dr. Freeman also spoke of the relative advantages of the general hospital and the special hospital for children and stated that the general hospital offered the pediatrician the advantage of contact with men in other departments and he could thus get acquainted with methods that were being employed with adults and that might be applied to children as well.

Dr. L. E. LA FETRA of New York said that there were many other factors besides the cubic air space that had to do with the welfare of infants in institutions. The fewer babies there are to a given amount of cubic air space the better they did. Breast-fed infants did better than those artificially fed with the

same air space. The amount of indivdual care the babies received was an important factor. When more babies were admitted to a ward more nurses were too often not added. Frequently there was inadequate nursing at night. Beds should be far enough apart to avoid the danger of cross infection.

Dr. S. McC. Hamill of Philadelphia discussed the advantages of general and special hospitals for children and said the question really resolved itself into one of hospital administration.

Dr. Henry L. Coit of Newark brought out the point that atrophic babies radiated heat rapidly and with this type of infants one had to be more careful as to the ingress and egress of air; for these infants the air should be warmer than for normal infants. For such infants a proper balance in the atmospheric conditions could not be obtained by window ventilation. In determining air space some allowance had to be made for the physical condition of the child and its capacity for maintaining heat.

Dr. Fritz B. Talbot of Boston took exception to Dr. C. Coit's statement that atrophic infants radiated heat more rapidly than normal ones; they had found that in atrophic infants the subnormal temperature was not due to radiation from the skin but to the fact that the engine did not make enough heat to keep up the temperature; and heat had to be supplied from the outside.

Dr. Samuel S. Adams of Washington, D. C., said that proper ventilation depended on many different factors; a competent architect was one of these. If one could not get proper hospital construction from the board of managers of the hospital, an appeal to the ladies' board was sometimes successful. They had adopted the plan of having the mothers come and take their babies out for exercise in the afternoons, and had also employed nurses for this purpose. The babies that were taken out undoubtedly did better than those that remained in-doors.

Dr. Southworth, in closing the discussion, said there was a growing belief that babies should not be kept in foundling hospitals, but were better off boarded out. The two states that were making the greatest effort to board out their babies were those in which the laws required the least cubic air space in institutions for infants, namely, New York and California.

Parapharyngeal Abscess as Distinguished from Retropharyngeal and Peritonsillar Abscess. — Dr. Henry Heiman of New York read this paper in which he described the distinctive features of each of these conditions and concluded as follows: There occurred, especially in children, a form of abscess which was occasionally mistaken for retropharyngeal abscess, but which had a separate and distinct entity. It might be called parapharyngeal abscess as its site was in the lateral columns, that was, by the side of the pharynx. The origin of this abscess was from the superior chain of deep cervical glands which were situated along the course of the carotid artery, as distinguished from the retropharyngeal glands, situated in the circumscribed retropharyngeal space, just lateral to the midline and in front of the prevertebral muscles. The parapharyngeal abscess always displaced the tonsil toward the median line and was rarely accompanied by any marked local change in the appearance of the pharynx, or by any symptoms of pressure on the larynx. These abscesses were, as a rule, cured only by external operation.

Dr. Wilder Tileston of New Haven, Conn., said he had just seen a case of parapharyngeal abscess, in which the abscess perforated internally, contrary to the rule Dr. Heiman laid down.

Dr. Thomas S. Southworth of New York said that peritonsillar and parapharyngeal abscesses were likely to be confused. In the peritonsillar abscess there was more swelling of peculiar vague character before we could feel the gland, but not an external fluctuating mass. The abscesses grouped under these two heads sometimes pointed inside and sometimes out. Dr. Southworth asked Dr. Heiman whether in his experience these parapharyngeal abscesses pointed externally, or whether one had to go down after them as after those secondary to scarlet fever.

Dr. L. E. La Fetra of New York said that he wished to add his testimony to what had been said, that parapharyngeal abscess could certainly be opened from within if the cases were such as he understood were included in the parapharyngeal group. One of the points was that in these cases in which there was a large amount of swelling and the tonsil was pushed inward toward the midline, one need not be in too great a hurry to operate; with expectant treatment, hot irrigations, etc., the abscess might open of itself.

Dr. Walter Lester Carr of New York, expressed the opinion that it would sometimes be found difficult to make distinctions according to this classification. He said he had heard this subject discussed and the surgeons were all in favor of an external operation while the medical men thought these abscesses could be reached internally, or could be brought to a point by irrigations. The paper had not told them definitely when a case was suitable for the surgeon and when it was proper to use a small incision, an operation such as could be done by any of them. The operation which gave the best drainage, whatever the form of infection, was the preferable one.

Dr. J. P. Crozer Griffith of Philadelphia stated that from his experience in consultations with general practitioners he had been led to believe that the diagnosis of retropharyngeal abscess was not as easy as Dr. Heiman had said.

Dr. Heiman, in closing the discussion, showed that most of the points brought up had been covered by his paper. Parapharyngeal abscess was much slower in developing, while the peritonsillar abscess developed within from twenty-four to forty-eight hours, and involved Rosenmuller's fossa.

A Contribution to Ductless Gland Therapy. — Dr. Royal Storrs Haynes of New York presented this paper in which he related the history of an abnormal child which demonstrated the particular activities of the pars intermedia of the pituitary gland. This patient was first seen in 1905 when three years and eight months of age, and a diagnosis of cretinism was made. Under thyroid therapy she improved until at the end of two years she was bright, intelligent, with a closed fontanelle and not greatly protuberant abdomen. Shortly after this it was noted that she was not so bright. Under increased doses of thyroid she again deteriorated. In 1913 she came under the direct care of the writer, at which time she was a large child, though below the average. She was excessively nervous, had an excessive appetite and was troubled with enuresis. It was apparent that she was getting too much thyroid. After doing without thyroid for some months she became remarkably normal. During the past six months it seemed that another agency was at work or released by the withdrawal of the thyroid. The patient's weight increased rapidly. Her face was heavy, her fingers blunt and she looked old and sullen. The possibility of pituitary involvement suggested itself and a radiograph seemed to show that the sella turcica was enlarged. Acting on the suggestion that an enlarged turcica meant an enlarged pituitary, while the increased tolerance for glucose meant a deficient pars intermedia, he concluded that a hyperplasia of the pars anterior caused the enlargement of the face, hands, and feet, and that this by pressure on the pars intermedia or its blood supply caused it to become deficient. Acting on this supposition a preparation of pars intermedia was obtained in capsule form, each capsule being equivalent to 150 pounds of live bullock. After taking these capsules for two weeks the patient began to show an improvement and made steady progress until at the end of some months a distinct change had taken place in her facial expression and her skin. Her fingers became tapering, her hips slender and shapely and her lower extremities straighter. An attempt was made at one time to resume the thyroid treatment but this had to be abandoned. The patient did not now appear to be an abnormal child, only a rather heavy stocky one, good natured and insensitive to pain. It seemed evident in this case that, assuming deficiency of thyroid, there was also an affection of the pituitary, which partook of the nature of deficiency of the pars intermedia.

Dr. Charles Herrmann of New York said that this case bore out his contention that frequently more than one ductless gland was affected. There seemed to be a correlation between the so-called ductless glands. Assuming this to be the case an extract composed of thyroid, suprarenal, and pituitary was better than thyroid alone. In the treatment of cretinism itself, they had formerly used only thyroid extract, but they were now using thyroid protein and the results were as good if not better than with the thyroid extract.

Dr. J. P. Crozer Griffith of Philadelphia said he had under his care a boy who had gigantism and both a hypo- and a hyper-activity of some ductless gland. He did not see how this could be unless there was something besides the pituitary diseased.

Dr. HAYNES replied that there might be an association of thyroid and pituitary disease. There was a scientific basis for this statement, since the removal of the thyroid had been shown to result in hyperplasia of the pituitary.

The Energy Metabolism of an Infant with Congenital Absence of the Cerebral Hemispheres.—Dr. FRITZ B. TALBOT of Boston made this report. He said that this baby was admitted to the Massachusetts General Hospital when eight months of age, at which time he was unable to sit or hold his head up. His muscles were relatively undeveloped, anterior fontanelle depressed, posterior fontanelle closed. The child was blind, apparently deaf, and had an idiotic expression. There was no paralysis other than the muscles of the neck. His reaction to touch seemed more highly developed than in the normal infant. An operation for the relief of the blindness showed that the hemispheres of the brain were entirely absent and were replaced by cerebrospinal fluid. At the base of the skull there were a series of knobs, none larger than a small walnut, the posterior of which probably represented the cerebellum. The pulse rate when the child was at rest was 69 to 70 per minute; during muscular exercise it was 140 per minute. The child weighed 330 grams more than the average baby of the same age. The metabolism of the child was determined in the apparatus described by Benedict and Talbot, in "Gaseous Metabolism of Infants" (Carnegie Institute, Washington, Pub. 210). A comparison of the metabolism of this child with that of two normal infants of about the same age, weight, and length showed that the metabolism of this child was extremely low. His minimum metabolism was relatively lower than that of a new born babe and of several fat babies none of which produced less than 42 calories per kilo body weight. Since this child was deprived of the volitional areas of the brain, his life was similar to that of a frog in which the cerebral hemispheres had been removed. He therefore did not develop musculature as would a normal infant. His temperature remained constant during the time of observation. The vital functions of this infant were carried on at a very low plane because his existence was purely reflex. Unless some external stimulus caused him to move there was little or no muscular activity and as a result only a small amount of fuel was necessary to keep the furnace going.

Dr. JOHN HOWLAND of Baltimore stated that in his metabolism studies he had reported a similar case in a child eight years of age when first seen and weighing only 13 pounds. His metabolism was very low and he had almost no muscles. The results of the metabolism observations made on this child were nearly comparable to those presented by Dr. Talbot.

Dr. TILESTON of New Haven, Conn. asked whether the child had had any epileptiform seizures, chronic spasticity, tachycardia, or increased respiration.

Dr. TALBOT of Boston replied that there were no changes in the respiration and no nervous symptoms except that when the child cried he made a sound suggestive of laryngismus stridulus.

(*To be continued.*)

STATE BOARD EXAMINATION QUESTIONS.

WASHINGTON STATE BOARD OF MEDICAL EXAMINERS.
July, 1914.

[Answer ten (10) questions only in each paper.]

(*Continued from page* 382.)

GENERAL DIAGNOSIS.

1. How would you diagnose an acute attack of appendictis? Differentiate between an acute attack and an un-ruptured ectopic gestation.
2. Describe the cardinal symptoms of exophthalmic goitre. When should you operate and what are the dangers in operating?
3. Describe burns of the first, second and third degree. What complications are likely to arise in the latter class?
4. Describe the symptoms of intestinal obstruction and differentiate from stone in the ureter?
5. Give differential diagnosis between concussion and compression of brain.
6. What sequel frequently follows depressed fracture of skull? How would you locate such by symptoms in the superior parietal region?
7. Differentiate between tabes dorsalis and multiple sclerosis.
8. Differentiate between pleuritic effusion and gangrene of lungs.
9. Differentiate between acute albuminuria and interstitial nephritis.
10. Describe acute otitis media, and what complications are likely to arise?
11. Give diagnosis between Landry's paralysis and rabies?
12. Describe symptoms and name causes of sacro-iliac disease. Differentiate from sciatica.

BACTERIOLOGY.

1. Give four methods by which microorganisms gain entrance to the body and name two diseases of each class.
2. Name the pathogenic agents in the following diseases: diphtheria, uncinariasis, syphilis, erysipelas, malaria (estivoautumnal), abscess, acute osteomyelitis, purulent salpingitis.
3. What is meant by infection? Give the usual symptoms.
4. Define following terms: chemotaxis, strict parasite, saphrophyte, opsonins, agglutinin, antiseptic, disinfectant.
5. Describe and give the characteristics of pneumococcus.
6. In a case of suspected diphtheria how would you arrive at a positive diagnosis? Describe process.
7. Differentiate between: vaccines and antitoxins; sapremia and septicemia; septicemia and pyemia.
8. What bacteria most frequently cause puerperal fever?
9. Give short description of Gram's method of staining and state which of following bacteria are "Gram positive": tubercle bacillus, typhoid bacillus, gonococcus, diphtheria bacillus, anthrax bacillus.
10. Describe the bacillus of typhoid fever and give characteristics.
11. What is a pure culture? Name five culture media in common use.
12. Give characteristics of the tubercle bacillus.

CHEMISTRY.

1. Define chemistry, atom; molecule; density.
2. Define carbon. Illustrate, (*a*) Free; (*b*) In combination.
3. What are hydrocarbons? Illustrate.
4. What gaseous matters are found in the body during health?
5. What is sodium chloride and daily amount eliminated?
6. What are curative sera and how prepared?
7. Give pigments of bile, blood, urine.
8. What is the caloric value of food? How serviceable in the dietaries of (*a*) Infancy; (*b*) adult; (*c*) old age.
9. Give quantitative estimation of total acidity of gastric contents.
10. Give four abnormal constituents of urine and method of determining same.
11. Give ferments of pancreatic fluid and their function.
12. Essential differences between human and cow's milk.

ANSWERS.

GENERAL DIAGNOSIS.

1. *Acute appendicitis* is characterized by sudden onset of pain, at first general over the abdomen, but later localized in the right iliac fossa; tenderness, most marked at McBurney's point; rigidity of the right rectus abdominis muscle; fever; vomiting and constipation; the patient generally lies on his back with the right thigh drawn up.

In *unruptured ectopic gestation*, there is a history of irregular menstruation, morning nausea, and breast signs; the pain is of a colicky character and may cause faintness; vaginal examination shows a movable mass on one side of the uterus.

2. The *cardinal symptoms of exophthalmic goiter* are: Exophthalmus, enlargement of the thyroid gland, tachycardia and tremor. Operation should be undertaken when the disease continues to progress in spite of proper medical treatment. The dangers in operating are: Hemorrhage, sudden death from dyspnea, injury to the recurrent laryngeal or pneumogastric nerve, and tetany.

3. *Burns of the first degree* are characterized by erythema, and local congestion of the skin; *burns of the second degree*, by vesication; and *burns of the third degree* by destruction of the skin. The possible complication of this last class are: Shock, sepsis, and ulceration of the duodenum (which may cause death from hemorrhage or perforation).

4. *Symptoms of intestinal obstruction:* Abdominal pain of an acute and severe type, constipation, vomiting which may become fecal, prostration, pallor, thirst.

In *renal colic*, the pain is agonizing, and is located in the kidney and radiates down the ureter, and may be felt in the testicle, glans penis, or inner side of the thigh; a chill is usually present; and the urine is bloody.

5. *Differential diagnosis of concussion and compression of the brain:*

	CONCUSSION.	COMPRESSION.
Onset	Sudden.	Gradual.
General condition	Can be roused.	Cannot be roused.
Pupils	Equal, react.	Dilated, immobile, perhaps unequal.
Pulse	Slow and weak.	Slow, full, heaving.
Respirations	Slow, shallow, irregular.	Slow, deep, stertorous.
Muscular system.	Relaxed (functional paralysis).	Organic paralysis.
Reflexes	Present.	Absent.
Rectum	Incontinence of feces.	Incontinence of feces.
Bladder	Incontinence of urine.	False incontinence.
Temperature	Subnormal, equal on the two sides.	Subnormal, rising in late stages; may be unequal on the two sides.

—(*Aids to Surgical Diagnosis.*)

6. Depressed fracture of the skull is frequently followed by compression of the brain.

The symptom locating it in the superior parietal region is paralysis of the muscles of the lower extremity on the opposite side of the body.

7. In *tabes dorsalis* the cardinal symptoms are: Loss of knee-jerks, lightning pains, Romberg symptom and ataxic gait, Argyll-Robertson pupil, numbness of the feet, a history of syphilis, and the slow onset of the disease.

In *multiple sclerosis*, the cardinal symptoms are: Intention tremor, nystagmus, scanning speech, exaggerated knee-jerks, ankle clonus, ataxia, rigidity in the legs, attacks of vertigo and apoplectiform and epileptiform seizures.—From Butler's *Diagnostics.*)

8. In *gangrene of the lung*, the offensive odor of the breath and the presence of lung tissue in the sputum are quite sufficient to differentiate this condition from pleuritic effusion (or anything else).

9. In *acute albuminuria* there is albumin in the urine, but none of the other symptoms of interstitial nephritis.

In *interstitial nephritis* the symptoms may be latent, but as a rule the general health is disturbed; headache, defective vision, lassitude, insomnia, dyspnea on exertion may be present. The urine may contain a little albumin or none at all, blood pressure is increased, the pulse is hard and incomprehensible, and the second aortic sound is accentuated.

10. In *acute otitis media* there is tinnitus, impaired hearing, pain (which may become intense), and fever. *Possible complications* are: Inflammation of the mastoid cells, caries and necrosis, phlebitis, meningitis, and cerebral abscess.

11. In *rabies* "the wound by which the poison was introduced, as a rule, rapidly heals, and for a time nothing happens to attract the patient's attention to the scar. In about six to eight weeks or so the scar may become painful and nervous disturbances manifest themselves. The patient becomes sleepless, peevish, irritable, and experiences a choking sensation about the throat. When the disease is fully developed there are intense muscular spasms, the respiratory muscles and those of deglutition being specially involved; but a more or less tetanoid condition may be observed in nearly all the muscles. There may be opisthotonos. The features may be horribly contorted or wear an aspect of extreme terror; the saliva is not swallowed, and as it collects in the mouth along with thick mucus from the congested fauces it causes noisy attempts at ejection, attended with great difficulty. The face is usually flushed or livid during the attacks and there may be raving delirium, delusions, and hallucinations. It should be noted that, though the patient is very thirsty, he is afraid to drink, as any attempt at swallowing brings on the spasms at once; even the sound of running water will excite the attacks. There is generally fever, the temperature ranging from 100° to 103° F. After from two to three days the patient may pass into the "paralytic stage," which, however, is more common in animals. He generally dies of exhaustion in from two to ten days after the development of the characteristic symptoms."

Landry's paralysis "is an acute ascending paralysis beginning in the legs, rapidly involving the trunk, diaphragm, and arms, ending fatally, and probably due to a toxic affection of the lower motor neurone."—(Wheeler and Jack's *Handbook of Medicine.*)

12. *Sacro-iliac disease* is of tuberculous origin. The *symptoms* consist of pain over the joint, increased by movement or standing. From pressure on the lumbosacral cord, pain may be referred to the leg. The leg can be moved without pain or limitation if gentleness is exercised; but pain is produced by compressing or forcibly separating the crests of the iliac bones. There may be apparent lengthening on the diseased side from pushing downward of the iliac bone on that side. Tenderness and swelling, or even an abscess, may be felt over the joint posteriorly, or the abscess may burrow and point in the lumbar region, groin, or ischiorectal fossa.

The diagnosis from sciatica is made by the absence of pain on compressing the pelvis in sciatica.—(*Aids to Surgery.*)

BACTERIOLOGY.

1. *Microorganisms may enter the body:* (1) By the *respiratory tract*, as in pulmonary tuberculosis and whooping cough; (2) by the *digestive tract*, as in typhoid fever and cholera; (3) by the *mucous membrane* of the *genital tract*, as in gonorrhea and syphilis, and (4) by the bite of an insect (transferred to the blood) as in malaria and yellow fever.

2. *Diphtheria* is caused by the Klebs-Loeffler bacillus; *uncinariasis*, by the *Ankylostomum duodenale* and the *Necator americanus; syphilis*, by the *Treponema pallidum; erysipelas*, by the *Streptococcus erysipelatis; malaria* (*estivo-autumnal*), by *Plasmodium præcox; abscess*, by *Staphylococcus pyogenes aureus, Staphylococcus pyogenes citreus, Staphylococcus pyogenes albus, Streptococcus pyogenes, Bacillus tuberculosis*, and others; *acute osteomyelitis*, same as *abscess; purulent salpingitis*, same as abscess, with *Micrococcus gonorrhea*, and *Bacillus coli communis.*

3. *Infection* is the morbid process caused by the successful invasion of the organism by pathogenic *microorganisms.* The *usual symptoms* are: Malaise, chill, fever, prostration, headache, rapid pulse; other symptoms vary according to the infection.

4. *Chemotaxis* is the property by virtue of which certain living cells approach or move away from certain other living cells or substances.

Strict parasite is a parasite which cannot lead an existence independent of its host.

Saprophyte is a microorganism which grows on dead matter.

Opsonin is that quality of a serum which makes a microorganism more susceptible to phagocytosis.

Agglutinin is something in the blood serum of an animal affected with a bacterial disease which causes the clumping of the pathogenic bacteria.

Antiseptics are agents which prevent or restrain putrefaction.

Disinfectants are agents which restrain infectious diseases by destroying or removing their specific poisons.

5. *Pneumococcus* is a spherical or oval coccus, encapsulated, non-mobile, non-flagellated, non-sporogenous, non-liquefying, often occurring in pairs, non-chromogenic, aerobic and optionally anaerobic, staining readily with aniline dyes and by Gram's method; its cultural characteristics are variable, some strains growing readily on ordinary media, some with difficulty, and some not at all.

6. A sterile swab is rubbed over any visible membrane on the tonsils or throat and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is

ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appears as short thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts. *Methods of culture:* The bacillus of diphtheria grows upon all the ordinary culture media, and can be readily obtained in pure culture. Loeffler's blood serum, particularly with the addition of a little glucose, is an admirable medium for the rapid growth of this bacillus. The medium should be alkaline and not less than 20° C.

The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are nonmotile, and aërobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

7. *Difference between an antitoxin and a bacterial vaccine:* "The antitoxic sera act directly upon the poison secreted by the living bacterial cell and neutralize its toxic property, while the bacteriolytic sera affect the bacteria themselves and destroy them or paralyze their action. Since the antibacterial sera are without effect upon the formed toxin, they are mainly useful in practice as a means of protecting against the bacterial invasion, while the antitoxic sera (*e.g.* diphtheria) may be employed to combat an infection already in progress. Broadly speaking, the latter are curative, the former protective."—(Jordan's *Bacteriology.*)

Sapremia is due to absorption of toxins only, and is characterized by a persistent high temperature, relieved at once by removing the source of the poison.

Septicemia is due to organisms multiplying in the blood, and characterized by a maintained high temperature, but not relieved by getting rid of the original source.

Pyemia is due to particles of blood-clot carrying organisms to parts distant from the original source, and there setting up abscesses. It is characterized by rigors, very high temperature, sweatings, and big remissions of temperature.

8. Bacteria which most frequently cause puerperal fever, are: *Streptococcus pyogenes, Staphylococcus pyogenes aureus, gonococcus, Bacillus coli communis, Bacillus aerogenes capsulatus.*

9. *Gram's method of staining:* Stain a cover glass preparation for two or three minutes in anilin gentian-violet. Wash in water. Treat with Gram's solution (iodine, 1 gram; potassium iodide, 2 grams; water, 300 c.c.) for a minute and a half, when the preparation becomes nearly black. Decolorize with strong or absolute alcohol for at least five minutes, wash, dry, and mount. Sometimes a contrast stain of Bismarck brown or eosin is used.

Tubercle bacillus, diphtheria bacillus, and anthrax bacillus are Gram positive; typhoid bacillus, and gonococcus are Gram negative.

10. The *bacillus of typhoid fever* is a short bacillus, with rounded ends, about 1 to 3 microns long by 0.5 to 0.8 micron wide, motile, flagellated, non-sporogenous, aerobic and optionally anaerobic, stains by carbol-fuchsin but not by Gram's method. The Widal reaction is obtained with the typhoid bacillus, a culture of which shows the phenomenon of agglutination or clumping upon the addition of dilute serum from a patient with typhoid fever.

11. A *pure culture* is one that contains only one kind of microorganism.

Five culture media: Gelatin, bouillon, blood serum, agar, and potato.

12. The *tubercle bacillus* is a small slender rod, about 3 or 4 microns long by 0.2 to 0.5 micron wide; it is nonmotile, has no flagella, no spores, is aerobic, and resists acids; stains well by Ehrlich's method or by carbol-fuchsin method. The bacilli grow well on blood serum and in glycerin bouillon.

CHEMISTRY.

1. *Chemistry* is that branch of science which treats of the composition of substances, their changes in composition, and the laws governing these changes.

An *atom* is the smallest particle of an element that can enter into chemical action.

A *molecule* is the smallest quantity of any substance that can exist in a free state.

Density of a substance is the weight of a given volume of that substance as compared with the weight of an equal volume of some other substance accepted as a standard of comparison, under like conditions of temperature and pressure.

2. *Carbon* is a chemical element, with atomic weight 12, valence 4, and symbol C. It exists *free* in three allotropic forms, diamond, graphite, and coal; in *Combination* it is found in every organic compound, such as ether, chloroform, chloral, phenol, carbohydrates.

3. *Hydrocarbons* are substances which contain carbon and hydrogen only, as methane CH_4; ethane C_2H_6.

4. *Gaseous matters found in the body during health:* Hydrogen, oxygen, nitrogen, carbon, dioxide, methane.

5. Sodium chloride is a compound whose molecule contains one atom of sodium and one atom of chlorine, NaCl. Abut fifteen grams are eliminated daily.

6. "Serum-therapy proper is the prophylactic and curative treatment of certain infectious diseases by the subcutaneous or intravenous administration of a blood-serum containing an antibody (antitoxic, bactericidal, etc.) which is specific to the particular disease. As generally used, however, the term includes also the treatment of some of these affections by vaccines and by the toxic products (toxins) of attenuated cultures of their respective microbes; but these toxins, though sometimes grown on blood-serum, may be produced on other media, and are never administered in a blood-serum, as the antibodies invariably are.

"An *Antitoxic Serum is prepared* as follows: A highly virulent culture of the specific microorganism of the particular disease, or still better, a strong toxin of tested strength prepared therefrom, is injected into the cellular tissue of a suitable animal, generally a horse, at first in very small quantity. The effect is soon shown by the onset of fever and other symptoms of acute disease, which are known as the 'reaction.' After an interval of time sufficient for recovery from these symptoms, the injection is repeated with a stronger toxin or with a culture of greater virulence, or with a larger quantity of the original toxin. This process is continued for several months, or until the animal no longer 'reacts' to the poison, and then sufficient antitoxin is presumed to exist in its blood to render it immune to the toxin and to the disease. After each inoculation the animal's blood serum is tested as to its value by experiment on guinea-pigs of definite weights. When the desired degree of immunity is reached the animal is bled from the jugular vein under strict aseptic precautions, from 6 to 12 pints being taken from a horse, according to his size and general condition. The blood is received in sterilized flasks, which are carefully stoppered and stored on ice until the clot has separated from the serum. The latter is tested to determine its value in antitoxin, has phenol added to it in the proportion of 0.5 per cent, and is bottled in vials which contain in each the dose for one patient. The vials are labeled with a statement of the number of normal antitoxin units per c.c. of the contents, expressed in multiples of a standard normal serum."—(Potter's *Materia Medica.*)

7. PIGMENTS. Of *bile:* Bilirubin, biliverdin, bilifuscin, biliprasin, bilihumin. Of *blood:* Hemoglobin, oxyhemoglobin, hematin. Of *urine:* Urochrome, urobilin, uroerythrin, uroxanthin.

8. "In order to supply the requirements of the organism a certain amount of potential energy is needed to over-balance the amount dissipated in waste and in the production of body-heat. More potential energy is consumed during work than when the individual is at rest. The following table, computed by Rubner, shows the daily heat consumption, in units of heat (calories), in an adult, weighing 65 kilograms:

During rest in bed	1800 calories	or 28 calories per kilo.
In repose	2100 calories	or 32 calories per kilo.
In light work	2300 calories	or 33 calories per kilo.
In moderate work	2600 calories	or 40 calories per kilo
In hard work	3100 calories	or 48 calories per kilo.

From Rubner's investigations we learn that:

1 gm. of protein	= 4.1 calories
1 gm. of fat	= 9.3 calories
1 gm. of carbohydrates	= 4.1 calories

It has also been determined that 1 gram of alcohol equals 7 calories. In other words, the number of grams of proteins, fats, and carbohydrates required daily can be converted into their calorimetric equivalents, and inasmuch as the alimentary principles can in a degree be substituted for one another (law of isodynamics), the daily food requirements can be easily estimated in calories of heat. Thus, in order to calculate the caloric value of any food in preparing a dietary, the number of grams of proteins contained are multiplied by 4.1; the number of grams of fat by 9.3; and the number of grams of carbohydrates by 4.1; the total is then ascertained by adding. Bearing the weight of the individual in mind, a dietary can easily be constructed according to the following method:

The quantity of protein consumed daily is	100 gm. × 4.1 =	410
The quantity of carbohydrates consumed daily is	500 gm. × 4.1 =	2050
The quantity of fats consumed daily is	50 gm. × 9.3 =	465
		2925

The average number of calories required daily in an individual, according to this calculation, is therefore 3000."—(Friedenwald and Ruhräh's *Dietetics for Nurses.*)

9. *Estimation of total acidity of gastric contents:* "To 10c.c. of the filtered fluid, accurately measured into a beaker, three drops of a 1 per cent solution of phenolphthalein is added, and enough $\frac{N}{10}$ NaOH solution, accurately measured from a burette, to produce a permanent pink color. After the addition of a few cubic centimeters of the decinormal soda solution, a light rose color appears, which should not be mistaken for the end reaction. The final change of color is produced by a single drop of the alkali, and hence the addition should be made drop by drop near the end. Near the completion of the test, each drop will produce a pink-red cloud as it falls into the liquid, which will disappear on gently mixing the contents of the beaker. This is best done by giving the beaker a rotary motion."—(Bartley's *Chemistry.*)

10. First of all, test for the *albumin*, as follows: The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid the urine is simply heated to near the boiling point. If the urine be neutral or alkaline it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

If albumin is present it should be removed. The urine is then tested for *sugar* as follows: Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for *bile:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

Test for *Blood:* To the urine add a solution of potassium hydroxide to distinct alkaline reaction; heat nearly to boiling (do not boil). A red precipitate is produced.

11. *Ferments of the pancreatic fluid. Trypsin*, which splits up proteins into proteoses, peptones, and amino-acids: *Steapsin*, which emulsifies and saponifies fats: and *Amylopsin*, which converts starches into erythrodextrin, achroodextrin and maltose.

12. Normal human milk consists of about 88 per cent of water and about 12 per cent of solids. These latter are approximately: proteins, 2 per cent; fats, 3 to 4 per cent; sugar, 6 per cent; and inorganic salts, about 0.3 per cent.

Cow's milk has approximately: proteins, 4 per cent; fats, 4 per cent; sugar, 4 per cent; and inorganic salts, about 0.7 per cent.

(*To be concluded.*)

Therapeutic Hints.

The Medicinal Treatment of Gastric Ulcer.—P. Cohnheim notes that there are two drugs of especial value in this condition, namely, nitrate of silver and subnitrate of bismuth. As a general rule the former should be given in the acute chlorotic ulcer, and bismuth in the other forms of ulcer, in the following prescriptions:

℞ Silver nitrate, gr. vij ss.
Distilled water ʒ vj ss.
M. et Sig.: One tablespoonful (porcelain) in a wineglassful of water ¼ to ½ hour before meals.

℞ Bismuth subnitrate, ʒ iij ss.
Sig.: One teaspoonful in a glass of warm water, stirred well, before breakfast. Lie on right side one-half hour after taking.

If the pain is not relieved by the above treatment it is best to prescribe belladonna combined with bismuth or an alkali one or two hours after eating, as follows:

℞ Extract of belladonna leaves, gr. iii—v.
Magnesium oxide,
Sodium bicarbonate, āā ʒ vj.
M. et Sig.: A teaspoonful one or two hours after meals, two or three times daily.

℞ Extract of belladonna leaves, gr. iij.
Bismuth subnitrate, ʒ iv.
M. et Sig.: A knifepoint after meals.

If there are spasms of the pylorus from one-half to one wineglassful of olive oil should be given in the morning before breakfast and from one to two teaspoonfuls before the midday and evening meals; or the following may be given:

℞ Tincture of belladonna leaves, ʒ j—j ss.
Sweet almond oil, ʒ j—j ss.
Yolk of one or two eggs.
Distilled water, q. s., ad ℥ vij ss.
M. ft. emulsio. S.: A tablespoonful before eating, t.i.d.—*Diseases of the Digestive Canal.*

A New Treatment for Chorea.—Sáinz de los Terreros bases this treatment upon the method of intravenous injections of bichloride of mercury as recommended by Huertas of Madrid in the treatment of rheumatic arthritis. In a choreic patient eight years of age the course of treatment would be as follows: Two intravenous injections of one milligram, two of two milligrams, and ten of three milligrams of bichloride of mercury, three injections being given every week. The results are said to be excellent.—*La Pediatría Española.*

Digitalis in Large Doses in the Treatment of Pneumonia.—Manfredi notes that this method of treatment has been employed by Maragliano since 1891 in his clinic at Genoa. Rasori and Tommasi were the first to attribute antiphlogistic properties to digitalis, and Traube perceived in the vasoconstrictor property of this drug a means of reducing the intensity of inflammation. In 1888 Petrescu of Bucharest reported the good results he had obtained in the treatment of pneumonia by means of large doses of digitalis. During 1913 and 1914 Manfredi treated a large number of cases of pneumonia according to the method of Maragliano, as follows: On the first day there is given four grams of digitalis in the form of an infusion, and in very severe cases this amount is repeated on the following day. With the diminution in the frequency of the pulse the quantity of digitalis is gradually decreased, and the administration of this drug is suspended when the pulse falls to normal or below it. —*Annali dell' Istituto Maragliano.*

SOME EVERY DAY INJURIES TO THE EYE, AND WHAT TO DO FOR THEM.*

BY RICHARD KALISH, A.M., M.D., F.A.C.S.,

NEW YORK.

CONSULTING OPHTHALMIC SURGEON, KNICKERBOCKER, CITY, ST. JOHN'S, LONG ISLAND CITY, AND SEA VIEW HOSPITALS.

THE enactment of a Workingmen's Compensation Law accentuates the necessity for an accurate knowledge of first aid to the injured, and in no department of the healing art is this of greater economic value than in injuries to the eye. The treatment first adopted largely determines the outcome, for no matter how trivial may be the injury, there is always the risk of ultimate disaster.

It is axiomatic that one who has lost the sight of one eye is from the very nature of his condition much more likely to suffer an injury to the other, and it is important to note that the loss of sight in one eye interferes with the wage-earning capacity, while that loss in both eyes may make of the sufferer a public charge. It thus follows that the immediate and proper treatment of an injured eye concerns the entire community, for an injury trifling in its nature may by neglect or unskilful treatment terminate in total loss of sight with destruction of the organ itself, while on the other hand the recuperative power of the eye is so great that by employing as much as is possible strict antisepsis, in addition to the recognized methods of treatment, many a damaged eye that in the past would have required removal can now be saved and sight retained.

Injuries occurring in the ocular district arrange themselves automatically in two groups, the one as regards location, the other as to gravity, and these may be defined as, first, those affecting the external structures or adnexa, and, second, those damaging the eyeball itself. This subject may be treated either topographically or from frequency of occurrence; a consideration from the anatomic or topographic standpoint, it seems to me, will be the lucid and practical one to follow.

Abrasions and contusions of the integument covering the lids resemble in appearance those occurring in other parts of the body, but they call for a different mode of treatment. The skin covering the eyelids is very thin, eroding easily, and antiseptics in germicidal strength will often cause its destruction, therefore carbolic acid solutions should never be stronger than one-half of one per cent., while those of bichloride of mercury should not exceed 1 to 5000, and tincture of iodine should not be applied at all. The classic "lead and opium" wash should not be used in treating contusions of the eyelids for it makes the skin stiff and hard, causing it to crack, and, whenever there is corneal abrasion, lead is deposited on this raw surface leaving a permanent white, dense, disfiguring scar which, if in the line of vision, interferes with sight. The proper remedies to use are weak lotions, many of them alkaline, such as, a 1 per cent. solution of biborate of sodium, a saturated solution of boric acid, a dilution of tincture of arnica, one drachm to an ounce of water, equal parts of colorless extract of witch hazel and water, and other solutions of similar nature. These may be applied either hot or cold, just as the patient prefers, and during their employment the skin should be anointed with cold cream or simple cerate several times daily.

The skin of the eyelids is so loosely applied that it moves freely in every direction and this laxity accounts for the rapid swelling that follows a direct blow which almost immediately produces great ecchymosis of these parts. This discoloration lasts about two weeks, is so unsightly, and is so often the cause of disagreeable remarks that its removal is urgently solicited. Once established, the ecchymosis cannot be dissipated and painting the surface is the only means of meeting this exigency. The many miscalled specifics such as arnica, calendula, witch hazel, raw beefsteak, cold oyster, scraped raw potato or turnip, and the medley of disgusting domestic remedies so popularly recommended, one and all, are without the slightest benefit.

If seen at once the best treatment is the application of a pad made of six or eight thicknesses of gauze saturated with a solution of boric acid and bandaged tightly over the eye. A folded handkerchief may be substituted for the bandage.

This laxity of the skin is employed advantageously in the performance of extensive plastic work to repair loss of integument, but these operations should be done under general anesthesia for so freely movable is the skin that immediately following subcutaneous injection of cocaine, a very marked edema arises by reason of which all the usual landmarks are at once obliterated.

Burns of the integument are best treated, not by the pasty and disagreeable Carron oil, but by the application of a 2 per cent. ointment of picric acid, which speedily relieves the pain, promotes healing, and leaves less scarring than Carron oil or any of the other remedies usually employed. Picric acid may also be used in watery solution 1 to 5 per cent., but as this stains bright yellow everything with which it comes in contact, the ointment is employed with more satisfaction.

Extensive laceration of the skin may cause great swelling or edema of the lids, sufficient sometimes, to produce so much pressure upon the globe as to threaten its destruction. When this occurs a canthotomy should be performed—the blunt-pointed blade of a pair of straight scissors is pushed under the outer commissure and all the tissues, including the skin, lying between the canthus and the margin of the orbit are divided with one or two cuts.

*Read before the Society of Alumni of Bellevue Hospital, June 2, 1915.

If the margin of the lid be torn or ruptured a suture should be so placed as to bring the separated edges into absolute apposition, otherwise one or more eyelashes may grow inverted, and with every act of winking scratch the cornea, provoking its irritation and an inflammation which may go on to loss of sight.

Wounds in the region of the punctum lacrimale should be carefully scrutinized as they often cause permanent damage to the lacrimal canal and sometimes its occlusion with the consequent overflow of tears which is so very uncomfortable and annoying. The punctum by manipulation, suture, or plastic replacement should be returned to its normal position in the lacrimal lake.

Injuries to the conjunctiva and to the structures of the eyeball are, as a rule, very painful, causing a blepharospasm so pronounced that an examination of the damaged tissues is well-nigh impossible and local anesthesia is imperative.

The writer emphatically dissents from the generally accepted dictum that in all ocular injuries requiring local anesthesia cocaine should be employed, and further, in his practice it is never used stronger than a 2 per cent. solution. Entirely too many eyes have been damaged or sacrificed by the perfunctory, profuse, and indiscriminate use of this remedy, therefore due caution must be exercised in its employment. Cocaine dries the cornea, loosens and promotes necrosis of its epithelium, thus favoring the occurrence of ulceration which so frequently results in partial or complete loss of sight. The conjunctival sac never is, nor can it be made sterile, and it affords a lurking place for numerous varieties of microorganisms, many of which are pyogenic, and to oppose which the intact cornea is the impenetrable barrier; but let there be any breach in the integrity of its epithelium and these microorganisms immediately invade the corneal tissue proper and start up an ulceration which eventuates in an opacity that may materially impair the sight, or even bring about its abolition. Holocain in 1 per cent solution is, in the writer's experience, the safest local anesthetic to use, having the advantage over cocaine that it does not dilate the pupil. The fact that it is considered more poisonous than cocaine may be discounted by carefully instilling it at the outer canthus, the head being inclined to that same side the surplus will then run over the cheek and not reach the nostril through the lacrimal canal and the nasal duct. Its solutions are not as permanent as those of cocaine and, like other substitutes therefor, cause some pain, but this burning and irritation soon pass away. Instead of holocain, alypin or novocain in 3 per cent., or beta eucain in 1 per cent. solution may be substituted; but whichever one is used the routine of its employment and the quantity to be used are the same: Two drops of the selected solution are instilled into the conjunctival sac and the lids closed—when possible the liquid should be allowed to flow over the cornea—two similar instillations are to be made at three-minute intervals, and in from three to five minutes subsequent to the third instillation full anesthetic effect is obtained. Even with the conjunctiva and cornea completely anesthetized it may not be possible to separate the lids, especially in children, in which event lid elevators should be used. With the thumb and forefinger grasp firmly the eyelashes and when possible the lower edge of the upper lid and lift it away from the eyeball. Into this interpalpebral slit pass the arm of the elevator and draw the lid upward, the arm of another elevator may then be slipped over the upper edge of the lower lid, and a separation of the retractors will bring into view a large part of the globe; by sliding the elevators from side to side the conjunctiva may be freely examined. Pressure of these elevators accomplishes another purpose, namely, an inhibitory influence on the orbicularis which assists in keeping the eye open. In order to explore the conjunctiva of the upper lid and its retrotarsal fold thoroughly the upper lid should be everted. The patient looking downward, the operator grasps firmly the lower edge of the upper lid between the tips of the thumb and index finger of the right hand, the point of the index finger of the left hand, a pencil, or a probe is then pressed over the upper edge of the tarsal cartilage and the lid is thus turned over, exposing its under surface. Eversion of the upper lid by one hand may be performed by substituting the tip of the second finger of the right hand as the fulcrum, instead of the index finger of the left hand or a pencil or probe.

Injuries to the conjunctiva, short of destruction of its tissue, heal quickly, requiring only cleanliness and the instillation of a weak antiseptic lotion.

The conjunctival sac is often the recipient of foreign bodies, such as bits of steel, ashes, lime, sand, husks of grain, and other intruders. Their usual site is under the upper lid, which after being anesthetized should be everted and the interloper wiped away with a wad made by wrapping a bit of absorbent cotton around any convenient cotton carrier. If this fails to dislodge the foreign body it can be lifted from its resting place by a blunt spud.

The most destructive of all injuries to the conjunctiva, the cornea almost without exception being likewise implicated, are burns, especially those from chemical irritants, such as carbolic, sulphuric, and other mineral acids, unslaked lime and cement. Molten metal and caustic alkalies, too, claim their large percentage of disastrous results, while hot water, steam, blasts of flame and hot air, ends of cigars, cigarettes, and matches are less frequent causes. The severity of the symptoms depends upon the duration of contact, escharotic quality of the invader, and extent of damage sustained, *i.e.* the amount of tissue destroyed.

The chief symptom is intense pain with marked inflammatory reaction in which the lids participate, as shown by becoming greatly swollen and deep red, and it is often impossible to open them in order to discover what damage has been wrought. In this event, with lid elevators separate the lids and inspect the cornea, if this be involved use holocain and if not, use cocaine to the production of full anesthesia, in order that a thorough examination may be made. Burns from acids should be thoroughly douched with a mild alkaline solution, such as a 1 per cent solution of sodium biborate or bicarbonate, and if either of these be not at hand, with a stream of cold water from an irrigator held not more than 18 inches above the eye, the liquid being allowed to flow over, not strike, the affected structures until all of the irritant has been washed away. Lime may also be washed away because it has been conclusively demonstrated that the heat generated by the slaking is more than counterbalanced by the frigidity of the irrigating liquid. Pieces of lime or molten metal should be removed by forceps or a spud before douching. Burns from alkalies, such as ammonia, potash, etc., should be neutralized by a weak acid solution, such as a 1 per cent. dilution of vinegar

with water. Pain in the eyeball and swelling of the lids follow, therefore cold pads should be applied to the closed lids. Two and one-half inch squares of patent lint or of six thicknesses of gauze, chilled on a block of ice, are to be applied at one or two-hour intervals, for from three to six hours at a time —if the inflammation be intense they should be constantly applied—the skin of the eyelids being freely anointed with cold cream or simple cerate, and for the first twenty-four hours, two drops of sterile olive or castor oil should be instilled between the lids every hour, and continued every three hours until healing is complete. In extensive burns with considerable loss of tissue a 1 per cent. ointment of picric acid, with or without holocain, should be inserted into the conjunctival sac, four times daily, to relieve the pain, reduce the burning sensation, promote healing and in a measure modify the resulting symblepharon, particularly when the fornix has been destroyed by the escharotic. If no relief is experienced after cold has been employed for six hours, hot pads, as hot as can be borne, should be substituted because injured eyes display as much idiosyncrasy to applications, as do individuals to remedies. After a few days the healing process will be hastened by adding a mild astringent lotion to the other local treatment. A very satisfactory one is a solution of sulphate of zinc, one-half grain to an ounce of sterile water, 2 drops to be instilled three times daily. When both the palpebral and the ocular conjunctivæ or the conjunctiva and cornea are eroded, extraordinary care must be exercised to prevent union of these denuded surfaces by reason of which the eyelid and the eyeball would become firmly bound together. When this occurs it causes a pulling on the eyeball and a sense of great discomfort that interferes with vision not only because of the corneal opacity, but also by restricting the movement of the globe, from cicatricial adhesion and contraction which may cause inversion of the edge of the lid with distressing trichiasis or its eversion with undue exposure of the cornea and its subsequent destruction. To prevent such an unfortunate result the raw surfaces should be separated by a silver probe at least three times daily, and the sterilized oils or picric acid ointment employed as above directed. This treatment will interpose a protecting layer between the raw surfaces, preventing their adhesion and must be employed until healing is complete. Under no circumstances should an occlusive bandage be applied, the eye must be left open because the retention in the conjunctival sac of purulent and irritative secretion increases the pain and retards the healing. If for any reason—as in children—a bandage must be applied, it should be removed every three to six hours, and the retained secretion washed away by irrigation. Despite this treatment symblepharon may ensue and a more or less extensive operation with or without transplanted flaps or grafts will be demanded.

Gunpowder injuries require local anesthesia, as above described, remembering that if the cornea be implicated, which is usually the case, holocain should be used. All grains of powder should be removed with a sharp spud, and if the grains are well within the conjunctiva they may be grasped by a forceps and with a scissors snipped off. When the cornea has been invaded two drops of a 1 per cent. solution of atropine should be instilled two or three times daily until the corneal irritation has passed away. The subsequent treatment of these injuries is the use of a weak solution of sulphate of zinc.

The cornea is one of the most important tissues in the entire body, and any interference with its transparency produces a loss in the economic value of the individual that is disproportioned to the extent and nature of the injury; therefore the value of an undamaged cornea cannot be overestimated.

Abrasion of the cornea by any scratching, such as occurs from a foreign body on its surface, under the upper lid, or from a twig or a finger nail, is a break in the corneal epithelium without damage to the substantia propria of the cornea itself. The pain is usually severe, there is considerable lacrymation and often a varying degree of photophobia. The treatment requires the removal of the foreign body, if one be present, the application of an occlusion bandage until the abrasion is healed and the instillation four times daily of a 10 per cent. solution of protargol or argyrol. If there be much conjunctival inflammation vaselin should be introduced into the conjunctival sac three times daily.

Corneal abrasion with subsequent erosion of the corneal substance, from an unusual cause, has several times been observed by the writer. In each case it was possible to exclude every cause except that the anesthetist had touched the cornea in order to determine when anesthesia was complete. The common practice of slightly separating the eyelids and brushing the ball of a finger over the cornea thus exposed cannot be too rigorously deprecated. It is not necessary, however, to touch the eyeball at all; the light reflex is more valuable and reliable. The importance of an intact corneal epithelium has already been explained and is again mentioned only in order to emphasize its significance and thus guard against possible ruin to sight.

The most frequent cause of injury to the cornea is a foreign body on its surface or in its tissue and this occurs mostly among mechanics. These substances consist of particles of ash, cinders, coal dust, emery, iron, sand, steel, and sometimes wood. The effects and the treatment of gunpowder grains have already been considered. These injuries cause great pain unrelated to the size of the intruder and depend more upon its site than upon its bulk; attached to the cornea it causes less pain than when it is upon the conjunctiva. The acute pain is largely due to the sensitive conjunctiva brushing over the sharp edges of the intruding body. The initial requirement is to locate the interloper and the most successful means is by focal illumination. Local anesthesia, as above advised, should be produced, after which the patient is so placed that the eye is lighted from one side only, the rays from day or artificial light being concentrated by a 3-inch lens into a cone of light, the point of which impinges on the cornea, a limited area is thus brightly illuminated while the surrounding region is dark. By changing the position of the illuminated area or by directing the patient to move the eye slowly in various directions, the entire surface of the cornea may be examined. The electric lighted spud is an exceedingly valuable and accurate means of locating the foreign body. It fulfils every requisite as it illuminates only a small spot at a time, and the foreign body being located the spud is at the same time in position immediately to remove the intruder. If no foreign body can be found and the symptoms point strongly to one being present a drop or two of a fluorescine solution—2 per cent. fluorescine in a 3 per cent. watery solution of sodium bicarbonate—may be allowed to flow over the cornea, the lids then closed, and in two minutes the eyeball washed off with a

boric acid solution. The abraded surface and sometimes the intruder itself will be colored green and easily recognized.

In removing a foreign body from the cornea every manipulation should be as gentle as is consistent with thorough work, for a damaged cornea is a menace to the retention of sight. The larger number of these intruders can be displaced by a mop made by wrapping a bit of absorbent cotton around any convenient carrier; a wooden tooth pick makes a very useful one, and with this wad brush in every direction, if these attempts fail to dislodge the particle a blunt spud should be employed. The motion in its use is that of lifting not scraping, and this should be tried at every angle of the foreign body. This maneuver failing, a sharp spud should be employed. Due care must be observed to cause as little damage as possible to the corneal epithelium, and likewise not to perforate the cornea. Instead of the sharp spud a corneal curette is the safer instrument to use, notably by those not especially skilled in handling the eye. Iron and steel particles if hot, or if not at once removed, will soon be surrounded by a ring of stained corneal tissue which should, whenever possible, be entirely removed, a scraping motion being sometimes required; the pointed hook of the corneal curette, or the point of the sharp spud will often remove this ring *in toto*. In every case in which the epithelium has been disturbed the eye should be lightly bandaged until the denuded surface has been covered in with healthy epithelium, restoration being established in from two to five days. Instillations of a 10 per cent solution of protargol or argyrol, two drops three times daily, should be practised until the cornea is healed. If the corneal tissue adjacent to the abrasion show evidence of inflammation two drops of a 1 per cent solution of atropine should be instilled prior to the application of the bandage, and this instillation should not be repeated unless the iris shows signs of inflammation, as evidenced by injection of the small circumcorneal blood vessels, photophobia, an irregular dilatation of the pupil and a muddy color to the iris. If the abraded surface exhibits no tendency toward healing and an ulcerative process has been established, the patient should be placed in charge of an oculist, for corneal ulceration, unless carefully handled and sometimes even when most skillfully treated, will result in loss of sight and perhaps of the globe itself. Extensive burns, corneal ulceration from any cause, together with perforating and penetrating wounds of the eyeball fall within the domain of the ophthalmic surgeon as they demand absolutely special treatment, such as cauterization, actual and chemical, subconjunctival and intraocular injection, intraocular insertion of medicated pencils, etc., consequently their consideration has no place in this paper and they are therefore omitted.

In conclusion, let it always be borne in mind that even a trivial injury to the eye is of as much importance as if it were more formidable in degree, also that no matter how trifling the damage may appear to be, it demands the same skill and care in its treatment as if it were of the gravest nature.

When this careful consideration has been adopted for every injury to the eye, many damaged ones that heretofore have been doomed to disaster will be saved from loss, and a successful and gratifying advancement in the conservation of vision will have been accomplished.

EPITHELIAL FUNCTION IN RELATION TO DISEASE.

By OWEN PAGET, M.D.,

FREMANTLE, WEST AUSTRALIA.

John Hunter and Sir James Paget in England, Professor Rokitansky in Vienna, and Professor Virchow in Germany removed pathology from the arena of idle speculation, and placed it on a sound morbid anatomy basis. The great French school of the Pasteur Institute, comprising Pasteur, Roux, Metchnikoff, Laveran and many others, conferred enormous benefits upon mankind by a strict attention to facts and careful exactitude in experiments. With such precedents one is diffident in proposing that speculative thought and inductive reasoning be brought to bear on pathology.

But it must be borne in mind that attempts to explain common occurrences, ignored or slighted by present-day theorists, may do much to assist clinical physicians. In a series of articles in the *Australian Medical Gazette* (1914-1915), the nose has been regarded as an organ of preventive medicine, capable not merely of protecting but also of immunizing against disease.

The subject has been further elaborated in a paper, "The Prevention, Treatment and Cure of Tuberculosis," published in the Medical Record. In this article it is claimed that the nasal epithelium has a curative capacity, even after disease has been acquired. Though not considering that these theories and experiments are proven, until they have stood the tests of time and experience, I yet feel justified in laying down the hypotheses that: (1) Nasal epithelium is able, otherwise than mechanically, to protect the body against disease. (2) It is able to immunize against disease. (3) It is able to cure or at least strongly modify disease already acquired.

Holding such beliefs, the attention turns to the intestinal epithelium, which is in constant relation with bacteria. To those who have operated as abdominal surgeons, that characteristic of our human economy, which makes feces inocuous when resting on the epithelium of the inside of the intestine, and a fierce menace when resting on the serons cells of the outside, shows without further comment that the lining cells of the intestine are at least passive resisters of microbes. Humanity at large is habitually interested in drugs, which professors of materia medica state have actions on the intestinal epithelium.

The Army, the Navy, and the Civil Hospitals alike restore to health a large proportion of their clientele with mistura alba. Such patients are said to suffer from constipation, a word which conveys a mental picture of feces obstructing the colon.

How often is such a condition of partial impaction seen by the abdominal operator, or the post-mortem demonstrator?

The virtues of Carlsbad and kindred places are ascribed to the presence of radium in the waters. It is less irresponsible to propose that they benefit their visitors through the action of their salts on the epithelial cells of the intestine. Professor Metchnikoff restores our debilitated health, and retards old age by feeding us on the Bulgarian bacillus. The physician of experience commences his treatment of a fever with a purge. Sir Arbuthnot Lane, with a vast surgical experience, considers that he markedly influences and even cures disease by his operations on the colon.

Since for long periods of time we are in good health, it is certain that the normal interaction between bacteria and intestinal epithelial cells is not harmful.

But just as in the case of the nose a proper circulation of air is necessary so that it may fulfill its functions towards bacteria, in the same way it is essential in the case of the intestine that there be a proper physiological rate of fecal flow. Interference with this causes an embarrassment to the activity of the cells, and their overthrow by microbic elements. Persons exposed to a common typhoid infection react differently. Some do not take the disease, others are severely infected, and there are an infinite number of grades between. It is as sensible to suppose that these differences are due to variations in the resisting power of the epithelium, as that they are due to the quantity or virility of the microbe ingested.

That women of the better-to-do classes, suffering from tuberculosis, who swallow their sputum from motives of delicacy, apparently hold the disease well in check, is well known. This in some cases probably leads to a cure.

At one of the hospitals for tuberculosis the following experiment was carried out in order to ascertain the cause of tuberculous ulceration of the intestine. Sixty advanced cases were selected. Of these thirty were told to swallow their sputum; thirty not to do so. All were autopsied. Of the thirty who swallowed their sputum, none had tuberculous enteritis. Of the thirty who did not, a large percentage were affected. A recent paper in the *British Medical Journal* advises the sucking of the septic wounds as a curative agent. This is, of course, employed by animals. It seems, therefore, as if the hypothesis put forward with regard to nasal epithelium having preventive, immunizing and curative action against disease had collateral support when the intestinal epithelium is studied from the same standpoint. Whilst such views help to explain the benefits of such simple drugs as the sulphates and carbonates of magnesium and sodium, they also suggest the advisability in epidemics of cholera of feeding contacts with sterilized cultures of the bacilli.

Assuming that the nasal and the intestinal epithelium have protective, immunizing and curative properties, what reactions take place in the greatest of all epithelial organs, viz., the skin, in the infectious diseases? Syphilis and gonorrhea are instructive examples to consider first. Their causative agents are known. The exact time of infection can in a large number of cases be definitely ascertained. Freely admitting that horny epithelium offers considerable mechanical protection against syphilitic infection, there is still a resistance not dependent on these superficial cells, but on the deeper layers of the epithelium.

It was not until the third attempt that Dr. Cory's unfortunate vaccination experiments were successful. Furher light on the matter has been thrown by the magnificent results achieved by the United States Naval Department in the prevention of this disease. It is hardly worth while to labor the question too much, because in the case of gonorrhea it is obvious. No one would suggest that gonorrheal infection is the result of a scratch or chafe of the urethral epithelium.

Now the moment of infection and the moment of practical expression of the disease being known, the period of resistance to disease or the incubation period is the intervening space of time. This cannot be other than the period during which the epithelium is capable of resisting, or even throwing off the disease. When this resistance breaks down it is shown locally in syphilis by the appearance of a sore and leucocytosis; or as a catarrh in the case of gonorrhea, whilst generally it is expressed by a feeling of malaise.

Practical experience shows that according to the vitality and capacity of the epithelium, proportionate of course to the virulence of infection, a disease is totally, partially, or feebly resisted.

Understanding the meaning of the "incubation period," and believing in the curative properties of epithelium, how can they be applied to such common disorders as scarlet fever and measles? The end of the incubation period of these diseases is locally expressed by the sore throat and running nose respectively. The general infection is felt as a malaise. Now the most striking phenomena in these two diseases is the rash, and if the skin is regarded as an organ capable of curing disease, this hyperemia, not inflammation, has a definite purpose. In other words, the rash is not a mere symptom, it is a definite and purposeful attempt on the part of nature to cure the disease. Since to many such an idea will seem far-fetched, the paths which have led me to such an assumption, will be here recapitulated.

In the *Australian Medical Gazette* (1914-1915), it was pointed out that in the cases of pneumonia extraordinary efforts are made to breathe through the nose. As in a large proportion of cases these people were unable to breathe through the nose when well, it was obvious that these efforts were not made by nature to obtain more air, since it was easier to do so by opening the mouth, but for some other purpose. Other observations had shown that breathing through the nose seemingly conferred immunity against certain diseases. Experimentally the sniffing of dried tuberculous sputum into the nose, provided this organ was made physiologically correct, had markedly beneficial effects upon the disease.

Carrying on the argument to the intestinal epithelium seemed to increase rather than decrease beliefs in the capacities of fixed cells to even cure disease. Applying the hypothesis to that enormous epithelial organ, the skin, the striking but unexplained phenomenon of the rash conforms to the proposition.

The most informative essay on the immunity of the skin is Sir James Paget's lecture on blood-poisoning (*Lancet* 1871). It seems as if there is at least sufficient to justify such an hypothesis as: "Epithelium is a factor in resisting, immunizing against, and even curing disease."

Epithelium and leucocytosis are not our sole protectives against disease. The former, however, is very important, and has up to now been neglected.

Other agents will not be referred to in this paper, the sole object of which is to attempt to place the commonsense knowledge of physicians on some sort of a scientific basis.

Questions of interest which now arise are: (1) Is the epithelium of one organ more specialized against any given disease, than the epithelium of another organ? (2) If the epithelium of one organ becomes incapacitated, can its functions be carried on by the epithelium of another organ?

My personal opinion as regards the first is that it is probable. For instance, the nose seems to

have higher capacities against diseases of the lungs than either the skin or the intestine. On the other hand, this does not mean that the skin and intestine have no powers against diseases of the lungs. The night sweats of phthisis, the burning skin and sweat of the crisis of pneumonia seemingly negative this.

Leaving the first question in abeyance, what evidence is there of interchangeable or assisting powers in the skin, the intestine, and the nose?

Crude savages and our ablest physicians alike pay attention to the condition of the skin and bowels in cases of fever, and prescribe accordingly. According to writers of textbooks on diseases of the skin, attention to the bowels is the most efficacious method of treatment in almost all of these complaints.

Confirmation of these ideas is found in my experiments on tuberculosis. If a tuberculosis derelict is put under treatment, one of the earliest signs of improvement is in the skin, which loses its muddy appearance. Especially is this noticeable in the conjunctiva.

It explains the use of poultices, blisters, putting the feet in mustard and hot water in cases of colds, and a thousand and one old-fashioned but effective home remedies, as also many drugs.

Having practised among Chinese, their belief in blisters has often struck me. The correctness of their opinions can, however, be shown experimentally. In an advanced case of malignant disease of the breast, which had been operated on to its utmost limits and afterwards *x*-rayed, there were in addition to the enormous growth numerous ulcerated scars. The patient was blistered over a healthy area. The fluid obtained mixed with saline solution was injected into the subcutaneous tissue. The cancer was unaffected, but the ulcerations showed marked and rapid signs of healing over, before the patient's death.

There is no wish in this paper to prove anything. It may possibly assist clinical physicians. The number of side issues is enormous. With the excitement and duties of the war it is difficult to write even in this sketchy manner.

Hopital Militaire 37A,
Dieppe, France.

SYPHILITIC ARTHRITIS.

By H. C. STEIN, M.D.,

NEW YORK.

ASSISTANT SURGEON DISPENSARY AND HOSPITAL FOR DEFORMITIES AND JOINT DISEASES.

Syphilis is responsible for about 20 per cent. of chronic joint diseases. Fifteen per cent. of joint cases seen at the Hospital for Deformities and Joint Diseases give a positive Wassermann test, and as the Wassermann is positive in only 80 per cent. of syphilis, we should infer that about 20 per cent. of cases of chronic joint conditions have their origin from syphilitic infection. Joint lesions are among the chief manifestations of syphilis. According to von Huppel, 56 per cent. of congenital syphilitics develop arthritis, and a large percentage in the acquired form. Many cases of suppurative bone and joint conditions of childhood are luetic in origin.

Owing to its frequency and the rapid improvement obtainable with specific treatment, the necessity for an early correct diagnosis is imperative. Yet, this group of cases is very often, if not in the majority of cases, incorrectly diagnosed by general practitioners. We see in this hospital daily, patients suffering from syphilitic arthritis who have been treated by various physicians and in various hospitals for years as suffering from rheumatism, rheumatic arthritis, tuberculous joints, Potts' and hip disease, malignancy, etc., without improvement.

The reason for so frequent failures of diagnosis in these cases is that the subject has not been sufficiently understood, and its frequency not realized until the Wassermann test came into use. The literature on the subject is very scant. The text books dismiss it very briefly. There is hardly any mention made of it in the medical schools.

The neuropathic Charcot joint occurring in tabes, the various bone manifestations as the localized periostitis, the local and diffuse hypertrophic osteitis, osteomyelitis, and epiphysitis, are well described and understood, and will, therefore, be omitted from this paper.

Syphilis is capable of producing almost every form of arthritis. These may be primary in the joint, or secondary to adjacent bone lesions. The form primary in joint are the arthralgias, acute, subacute and chronic simple synovitis, and gummatous synovitis. The secondary types result from neighboring bone lesions, as periostitis, osteitis, osteomyelitis, or epiphysitis, causng either a sympathetic synovitis, gummatous, or fibrous arthritis.

The classification of the various types is arbitrary and is made as to their clinical occurrence; certain forms are characteristic at certain ages; some are characteristic of hereditary syphilis, and others of the acquired form.

The clinical varieties are: (1) Epiphysitis with secondary joint involvement. (2) Hydrops. (3) Arthralgias. (4) Acute, subacute, or chronic synovitis. (5) Gummatous synovitis, primary or secondary. (6) Arthritis deformans type. (7) Chondroarthritis. (8) Mixed infections.

In hereditary syphilis, the type most common in the first year of life is that secondary to an epiphysitis, also called osteochondritis and pseudoparalysis. The process usually starts in the epiphysis of long bones, most commonly at the lower end of the femur, and the upper end of the humerus, as an irregular painful thickening caused by an increase in the number of cartilage cells. This interferes with its circulation and necrosis results, with later separation of the epiphysis into joint, suppuration, fluctuation, and discharging sinuses. Before the epiphysis separates, the joint effusion is serous. The limb affected usually is useless as far as power is concerned, and for this reason the condition is called "pseudoparalysis." As the condition favors the lower end of the femur and the upper end of the humerus, which are the important centers for growth of the extremities, there is often interference with the growth of the limb. This type is most commonly mistaken for tuberculous joints with sinus formation.

In children between the ages of eight and fifteen years, a simple symmetrical synovial effusion or hydrops is the usual occurrence. The knees are usually affected, either one or both. The condition is often intermittent following some systemic disturbance, such as sore throat, cold, etc. The swelling from effusion into the joint is variable in amount and is usually the only symptom. Pathologically, there are no changes except the effusion into the joint.

Arthralgias, or joint pains, are among the first manifestations of acquired syphilis and occur in the

larger joints in the early secondary stage, before the rash appears. There are no physical findings, no limitation of motion, but vague pains around the joints, worse at night.

In the later secondary stage, there is a condition resembling acute articular rheumatism, with high fever, multiarticular joint involvement with pain, tenderness, and swelling. The joints most commonly affected are the knees, elbows, shoulders, and sternoclavicular. There are no acid sweats, and no cardiac involvement. It may resemble gonorrheal rheumatism.

Subacute or chronic synovitis or hydroarthritis occurs in the late secondary stage, usually affecting one joint, and may be the remains of the acute type or develop gradually. The knee is usually affected. This condition is sometimes intermittent. There is but little pain, worse at night, slight limitation of motion, and a variable amount of effusion.

Gummatous synovitis (Frauenthal) occurs in both congenital and acquired syphilis. It is usually monoarticular and the knee is the favorite site. The process may be primary in joint or secondary to a gummatous periostitis. Those starting in bone produce the most destruction and greatest deformity. The condition starts as an irregular lumpy thickening of the synovia, with a variable amount of effusion into the joint. It resembles and is frequently mistaken for tumor albus. Gummata occur around ligamentous attachments and as villi protruding from synovial membrane into joint. These may break into the joint, causing suppuration and later sinus formation. The joint affected presents marked deformity from effusion and gummy masses, but limitation of motion is usually not so marked as appearances would indicate. Pains are not so marked but are worse at night. Remissions or almost complete cures with relapse are characteristic of this condition.

The arthritis deformans type is the most common form in acquired syphilis, but frequently occurs in the congenital forms. The condition is usually multiarticular, except when it follows an injury to a joint, when the monoarticular form is the rule. Joints subjected to strain, as in certain occupations, are the chief ones to be affected. In monoarticular forms, if syphilis exists, the synovite following an injury does not subside but becomes proliferative, and produces fibrous changes in the joint. In multiarticular forms, joints subjected to strain are affected, as the spine, elbows, wrists, and knees of bricklayers; spines of laborers; shoulders, elbows, wrists, and knees of laundresses, etc. The process may be gummatous, fibrous, or mixed, starting as an osteoperiostitis and spreading to perisynovial tissues, causing osteophytes, contraction of ligaments and tendons, producing limitation of motion with partial or complete ankylosis and deformity. Here again, pain is not a pronounced symptom unless there is much destruction; it is much worse at night. Limitation of motion is not so marked as the appearance of the joints indicate.

Chrondroarthritis occurs in congenital syphilis in children about fourteen. The chief feature is a recurring synovitis, with a chronic inflammation of neighboring bone, with pain and tenderness. Pathologically, it is a rarefying osteitis with deposit of caseous material in the cancellous tissue. It extends to the articular cartilage resulting in its grooving and pitting. The larger joints are favorite sites.

By lowering the resistance of joints, secondary infections are frequently implanted on the syphilitic base. Tubercle bacilli and streptococci from some focal infection are the germs commonly responsible for the mixed infections.

The symptoms of syphilitic arthritis vary with the types, but in general it may be said that the pain is not the leading symptom except in the acute forms and those accompanied by much bone destruction, and in most cases, it is worse at night; the limitation of motion is not so marked as the appearances would indicate, and tenderness is not marked. The joints subjected to strain or injury are most likely to become affected.

The diagnosis must be made from rheumatic arthritis, arthritis deformans, tuberculous joints, acute articular rheumatism, gonorrheal rheumatism, traumatic synovitis, and malignancy.

It depends upon (1) very careful personal and family history; (2) examination for concomittant signs of syphilis, as general adenopathy, keratitis, retinitis, iritis, Hutchinson's teeth, scars on tonsils, etc.; (3) Wassermann test; (4) luetin test; (5) the *x*-ray in many cases is an important diagnostic aid; syphilis usually causes hypertrophic changes in contrast to the rarefying changes of tuberculosis; (6) therapeutic test, whenever in doubt; specific treatment should be given in doubtful cases. If the patient is improved, it is reasonable to suppose that the condition is luetic; sometimes a negative Wassermann becomes positive when provocative treatment is commenced. The treatment is antisyphilitic.

Conclusion.—1. Syphilis of joints is of frequent occurrence and comprises about 20 per cent. of cases seen at the Hospital for Deformities and Joint Diseases.

2. It produces almost every form of arthritis and may be either primary in the joint or secondary to involvement of the adjacent bone.

3. It must be diagnosed from acute articular rheumatism, gonorrheal rheumatism, rheumatic arthritis, arthritis deformans, tuberculous joints, malignancy, and traumatic synovitis.

4. In infants, epiphysitis with secondary joint involvement is the most common type. In children from 8 to 15 years of age, hydrops or simple synovitis is the usual manifestation. The arthritis deformans type forms the bulk of cases occurring in acquired syphilis.

5. Pain as a rule is not severe and is worse at night.

6. Limitation of motion is not so marked as the appearances would indicate.

7. The diagnosis depends on history, concomittant signs and symptoms of syphilis, Wassermann and luetin tests, *x*-ray, and therapeutic test.

8. The possibility of syphilis should be considered in every case of joint disease of vague origin.

534 West One Hundred and Fifty-second Street.

Impairment of the Suprarenals in Scarlet Fever.—S. Dutoit reports three cases of scarlet fever in which a low blood pressure and symptoms of meningeal irritation pointed to an insufficiency of the suprarenals. Hutinel was the first to call attention to the frequency with which the suprarenals are involved in scarlet fever; giving rise to a clinical picture that suggests Addison's disease. With a pronounced lowering of the blood pressure there occur tachycardia and arrhythmia. The extremities become markedly cyanotic. The symptoms of meningeal irritation are particularly common. —*Klinisch-therapeutische Wochenschrift.*

DOES THE GENERAL PRACTITIONER UTILIZE THE MEANS AT HIS DISPOSAL FOR THE DIAGNOSING OF EARLY PULMONARY TUBERCULOSIS?*

By JAMES S. FORD, M.D.,

WALLINGFORD, CONN.

ASSISTANT PHYSICIAN, GAYLORD FARM SANATORIUM.

THE annual report of this Association shows that during the year 1914 over $20,000,000 was spent in combating and preventing the spread of tuberculosis. The question naturally arises, do the results obtained as "shown by a lowered death rate which is the final criterion by which the success or failure of the anti-tuberculosis campaign must be determined" seem to be commensurate with this immense sum expended, and if not, where does the fault lie? I believe that most men engaged in the work of prevention and treatment of this disease will admit that the results are not what they should be as regards this lowered death rate. True it is that during the past ten years the death rate has been reduced from 166.7 to 127.7 per 100,000, but it seems as though we should expect a greater cut when one thinks over the widespread and active campaign that has been waged against this enemy of the human race.

Ten years ago it was said that those among the general public suffering from tuberculosis consulted the physician only when the disease had reached an advanced stage and the chance of arrest was small or entirely lost. After these years of an active publicity campaign of education, no such indictment can be brought against the laity and we must seek the cause of this continued high death rate nearer our own door. It would not be at all amiss to ask is the general practitioner doing his share by utilizing all the available methods at his disposal for the diagnosing of early pulmonary tuberculosis, and having made the diagnosis, does he give the patient the proper advice as to his future course of life? I say the general practitioner because it is in his hands that most of these cases fall in the beginning.

In order to see just what was being done by the family doctor in his efforts to diagnose pulmonary tuberculosis correctly, and to advise those consulting him, I undertook a study of one thousand cases that had been admitted to the Gaylord Farm Sanatorium from October, 1907, to January, 1915, and I think that some of the figures and facts obtained are, to say the least, interesting.

In the study of these cases they were divided up into groups determined by the stage of their disease on admission, and these show the following:

There were 31 non-tuberculous cases (or 3.1 per cent. of the total number); 148 incipient cases (or 14.8 per cent.); 741 moderately advanced cases (or 74.1 per cent.); 80 far advanced cases (or 8 per cent.).

We undertook to find out how many physicians had been consulted before a diagnosis was made or before the patients applied for admission to the sanatorium.

Taking up first the 31 non-tuberculous cases, we found that they consulted 56 different physicians, of whom 37, or 66 per cent., made a physical examination only, one of these taking an *x*-ray picture in addition. Two others examined the patients through clothing; six, or 10.7 per cent., examined chest and sputum; six, or 10.7 per cent., examined chest, took temperature, but made no sputum examination; four, or 7.1 per cent., examined chest, took temperature, and examined sputum; three, or 5.3 per cent., made no examination whatever.

It certainly seems that something is woefully lacking when 6 per cent. of the physicians consulted make no examination whatever, and only 7 per cent. utilized all the methods at their disposal to make a correct diagnosis.

The figures obtained from the incipient class do not show up as well as this non-tuberculous group. Here we have 148 cases who consulted 254 physicians, of whom 160, or 62.9 per cent., made an examination of chest only, and 11 of these made this examination through the patients' clothing; two, or 0.8 per cent., took temperature only; three, or 1.1 per cent., examined sputum only; thirty-seven, or 10.7 per cent., examined chest and sputum, but did not take temperature; fifteen, or 6 per cent., examined chest, took temperature, but did not examine sputum; one, or 0.4 per cent., took temperature and examined sputum, but made no physical examination; seven, or 2.8 per cent., examined chest, took temperature, and examined sputum; thirty-nine, or 15.3 per cent., made no examination whatever, but treated the patients for various ailments as "run down," anemia, malaria, and "walking typhoid."

Here we have only 3 per cent. of doctors making use of most of the diagnostic methods available, while over five times that number made absolutely no effort whatever to find the seat of the trouble, but would, by their negligence or carelessness, allow a case with an excellent opportunity of arrest and a return to normal life go on to a far advanced stage. Nor does this condition of apathy as regards complete examination apply only to those who have been admitted to our institution.

Stoll,[2] in a study of 150 cases at Wildwood Sanatorium at Hartford, showed that of 37 incipient cases 35 per cent. were not examined on their first visit to their physician, but he does not say how many were not examined at all. Further on he says that of 147 cases, 16, or over 10.5 per cent., were never told they had tuberculosis until they entered the institution, though 75 per cent. of these cases had symptoms for at least five months before consulting their medical adviser.

Think of the amount of infection that such cases might spread, either because the physician consulted had not taken the time or trouble to find the underlying cause of his patient's complaint, or, if having found it, he neglects to lay down a few fundamental principles that could at least prevent the unfortunate victim of tuberculosis being a menace to his family and to the community at large.

Dearholt, quoted by Hawes,[3] in a study of 1400 cases of tuberculosis in the State of Wisconsin, showed that of 195 registered cases 60 either were not told the nature of their complaint or had their condition misrepresented to them by the first physician consulted, and of 159 cases not registered 91 were deceived or left in ignorance of their true condition. Hawes also shows in this same article that during the six months between August, 1903, and February, 1904, of 100 cases that had applied to the tuberculosis clinic of the Massachusetts General Hospital, but 15 were incipients and that 12 of these had a positive sputum before applying, making a diagnosis easy. From November of 1911

*Read before the National Association for the Study and Prevention of Tuberculosis, Seattle, Wash., June 15, 1915.

to May of 1912, of 100 cases coming to this same clinic, 30 were incipients, of whom 16, or 53.3 per cent., had a positive sputum, and were thus enabled to get an early start in their treatment.

In our incipient group but 38 physicians, or 26 per cent. of the 148 consulted, examined the patient's sputum; furthermore, 25 patients, or 16 per cent., of this same class, found to have a positive sputum on admission, had never had their sputum examined by their own physician. So we see that a large percentage of the general practitioners neglect to avail themselves of the opportunity of having a sputum examination made at no cost of money or effort to themselves. Frequently the diagnosis of pulmonary tuberculosis could be made by them weeks before it is, and these are indeed valuable weeks to the patient.

Our moderately advanced group consists of 741 cases, who consulted 1,468 physicians; 809, or 55.1 per cent., of these made a physical examination only, of whom 122 made this examination through the patients' clothes; 316, or 21.5 per cent., examined chest and sputum; 29 of this number made the physical examination without the patient removing his clothing; 88, or 6 per cent., examined the chest and took the temperature, but made no sputum examination, and 13 did not have the patients strip to the waist; 10, or 0.7 per cent., took temperature only; 11, or 0.7 per cent., examined sputum only; 2, or 0.02 per cent., took temperature and examined sputum, but made no physical examination; 106, or 7 per cent., made a thorough physical examination, took temperature, and examined sputum; 126, or 8.6 per cent., made no examination of any kind nor took temperature. There was absolutely no effort made to discover any abnormal condition, and you may rest assured that the advice given was in accordance with the examination.

I did not take into consideration the number of patients in this moderately advanced group that first consulted their physician for hemorrhage and who even then were told that there was nothing the matter with their lungs. It seems that even today many physicians have not learned that the spitting up of blood generally means tuberculosis, but will assure the patient that the blood comes from the back of the throat or any other conceivable place. There seems to be need of educating the general practitioner that hemorrhage is always to be considered tuberculosis, as Hawes says, unless there is clear evidence to the contrary. One of our cases consulted her physician for hemoptysis, and he, after listening to the history and without making an examination of any kind, told the patient that a diseased appendix was the cause of her hemorrhage and advised an immediate operation. There may be some excuse for a man who carefully examines his case but makes a wrong diagnosis, but there is absolutely no excuse for the man who takes neither time nor trouble to go over his patient.

The examination of sputum in the moderately advanced cases should be of great value to the physician, yet in these 741 cases 250 had never had a sputum examination before admission and 130 of these were found to have a positive sputum when they entered the sanatorium. Of the 1,468 physicians consulted but 425, or 28.9 per cent., thought it worth while to have a sputum examination made. Furthermore, as to the value of sputum examinations to the general practitioner may be cited the fact that there were 59 cases under treatment for various conditions for a period of one to thirteen months, during which time there was present both cough and expectoration, and yet the assurance was given that there was nothing the matter with their lungs until the sputum was returned positive. Barnes,[4] in 165 cases with expectoration, showed that the physician failed to diagnose tuberculosis accompanied by a failure to have the sputum examined in 31, or 18.7 per cent., and the delay in diagnosis by such failure was from two to ninety-six months, with an average of 10.3 months.

When 126, or 8.6 per cent., of physicians consulted make no attempt to make an examination of any type little progress can be made to wipe out this great menace to humanity. Barnes shows that of 66 cases 8, or 12 per cent., did not have their lungs examined by the physician first consulted and the delay in diagnosis was from two to twenty months, with an average delay of 5.1 months.

Even when we come to our far advanced group there is not the care taken to have the diagnosis made as promptly as it should be. We have studied the histories of 80 advanced cases, or 8 per cent. of the entire number, and obtained these figures:

They consulted in all 162 physicians; 79, or 48.7 per cent., made only a physical examination and 16 of this number made the examination through clothing; 1, or 0.6 per cent., took temperature only; 32, or 20 per cent., examined chest and sputum; 5, or 3 per cent., examined chest and took temperature; 16, or 9.8 per cent., examined chest, took temperature, and examined sputum; 29, or 17.9 per cent., made no examination of any kind.

In the last two items we are brought face to face with the fact that there are more men who make no examination whatever than there are men who are utilizing all the means at their disposal in their efforts to make a correct diagnosis.

Perhaps a summary of all our study at this time would not be out of place. There were, as I said in the beginning, one thousand cases, and these consulted 1,940 physicians, of whom 1,085, or 55.1 per cent., made a physical examination only, and of this number 151 did not deem it worth while to have the patient strip; 13, or 0.7 per cent., took temperature only; 14, or 0.7 per cent., made a sputum examination only; 381, or 20 per cent., made a chest and sputum examination; 114, or 6 per cent., examined the chest, took temperature, but did not make a sputum examination; 3, or 0.02 per cent., took temperature and made a sputum examination, but no physical examination; 133, or 7 per cent., made a chest examination, took temperature, and examined sputum; 197, or 10.2 per cent., made no examination of any kind.

Laverson[5] of California, in a similar study, made, however, on only 54 patients who consulted 72 physicians, got the following figures: 52.7 per cent. made only a physical examination, against our 55.1 per cent.; 12.8 per cent. made a physical examination and took temperature, against our 6 per cent.; 4.1 per cent. made a physical and sputum examination, but made no temperature record, against our 20 per cent.; 13.8 per cent. made no examination of any kind, against our 10.2 per cent. and Barnes' 12 per cent.; only 1 physician, or 2 per cent., took all the means necessary to make a diagnosis, against our 7 per cent.

The value of a temperature record appears to have been overlooked by the great majority of physicians consulted. Only 263, or 13.4 per cent., made use of a thermometer, and there is no doubt but that many of those who did not use one would

have obtained as much, if not more, information than they did with a stethoscope. The average practitioner should have it thoroughly impressed upon him that a continued afternoon or evening rise of temperature, in spite of the absence of physical signs or his inability to locate them, should at least make him suspicious of a tuberculous infection.

From these figures it can be seen that the attitude of the general practitioner in not making use of the routine measures of physical examination, taking temperature, and examining sputum is not confined to any one locality but seems to be widespread from the Atlantic to the Pacific.

The problem of the eradication of tuberculosis has been put wholly up to the physician, and Miller[6] said last year before the Canadian Medical Society that "it is not only the delay and ignorance of the patient in seeking advice, but the inability of practitioners to diagnose the disease in time that is today the greatest clog in the forward movement to meet and cope with tuberculosis." He also read replies received by him from the sanatoria men in Canada and a few in this country as to the average practitioner's ability to recognize (*a*) incipient, (*b*) moderately advanced, and (*c*) far advanced tuberculosis. The answers gave the general impression that the average practitioner rarely, if ever, diagnoses incipient tuberculosis. As to moderately advanced cases but one-quarter to one-half are recognized and then called incipient, and the ability to recognize far advanced cases is about on the same level as the moderately advanced type.

There is something radically wrong when a very large percentage of men in the practice of medicine are unable to recognize not only in its incipiency but even in the moderately advanced stage the most common disease on the face of the earth to-day. Why this state of affairs should exist is to most minds, I believe, unaccountable, and it must be put down in a great many cases to nothing more than carelessness.

The medical schools are not without blame for this above state of affairs, for until very recent years the teaching of tuberculosis was done wholly in a haphazard manner. Few if any of the men who acted as instructors in this disease had any special training either in its diagnosis or treatment; there were no special clinics for the patients suffering from tuberculosis nor was any attempt made to systematically follow up these unfortunate sufferers. Even to-day there are but a small number of medical schools in the United States that give an adequate course in tuberculosis, and up to one year ago but one school in Canada thought this disease of enough importance to have a chair for the teaching of it. Such conditions must be materially remedied if we hope to have the newly graduated medical men recognize incipient tuberculosis and to intelligently treat it.

Abrahams,[7] in a recent article on "Errors in Diagnosis," puts down those due to an incomplete examination as the most prolific cause of all, and he further states that many avoidable blunders result from this. He speaks, especially, of the haste with which physicians work; of not carefully examining the seat of trouble; that sometimes patients object to special examinations, and adds that it is far better to relinquish such a case, lose a patient, and save your reputation; he especially refers to the examining of patients through their clothing, and asks how it is possible in such cases to distinguish slight modification of breath sounds and to discern fine râles which are present in the early cases of tuberculosis.

It now seems as if there should be an awakening of the general practitioner to the part he is to play or should play in the overcoming of pulmonary tuberculosis and he should not be allowed to sit supinely by and see his cases left at home or sent to sanatoria in an incurable condition, when, by a little work on his part, such a case might have had a chance for an arrest and be able to return to his work and family.

Such figures as 133 men, or 7 per cent., of 1,940, making a conscientious effort to make a correct diagnosis by means of physical examination, taking of temperature, and examining sputum, against 197 men, or 10.2 per cent., who make absolutely no effort whatever to get at the seat of the patient's complaint, do not reflect any great credit upon the body of the medical profession. And as I have said before, this same percentage of conscientious and non-conscientious men as regards the diagnosing of tuberculosis seems to be the same in all parts of this country and Canada.

The advice given to most of these patients for whom the diagnosis was made was, in a majority of cases, of little value. They were told to stay in the open air, get an outside occupation, and to take eggs and milk. Absolutely nothing was said to them as to the amount of rest that they required, or anything told as regards the care of the sputum or the shielding of the mouth during coughing or anything else that would tend to lessen their being a source of danger to those with whom they came in contact. It is evident then that when the general practitioner does diagnose pulmonary tuberculosis he is unable to line out a systematic course of treatment for his patient.

These then are the facts as deducted from our study and now appears to be the time that the members of this association should seriously consider and devise some means of impressing upon the members of the medical profession the necessity of utilizing all the means at their disposal for the diagnosing of tuberculosis in its incipiency when the chances for arrest are excellent and so to drive this relentless and unmerciful foe of the human race from the face of the earth.

I wish to thank Dr. David R. Lyman for the use of his records and the encouragement given me in the preparation of this paper.

The Effect of the Thymus on the Leucocytes.—Gino Baggio has found that the injection into the growing or adult rabbit of aqueous extracts of the thymus causes an increase in the number of leucocytes, the increase being in the polynuclear neutrophiles and the lymphocytes, sometimes predominantly or exclusively the one or the other, and sometimes both to an equal extent.—*Archivio per le Scienze Mediche.*

ON THE USE OF THE TERM "PSYCHOANALSIS" AND ITS SUBSTITUTE.

By MEYER SOLOMON, M.D.,
CHICAGO.
ASSOCIATE IN NEUROLOGY, MAIMONIDES HOSPITAL.

THE terms "psychoanalysis" and "psychoanalyst" have become very familiar to all physicians, not to say many laymen, since the widespread dissemination of the Freudian theories. Psychanalysis is but an abbreviation of psychoanalysis. For this reason, and for euphonic and other reasons, I prefer the latter term. Psychoanalysis is, indeed, a good term, but it has been so much misused and abused that it is generally misunderstood and misapplied.

So far as I know, Freud was the first to introduce this now popular word. Owing to the numerous writings of Freud's followers, this word has found its way into diverse and far-distant lands. It is a term which seemed to speak volumes and was apparently seized upon by many with avidity and made a part of medical, especially neurological, psychopathological and psychiatrical literature.

So universally has this term been adopted that it surely seems to have made itself at home among many of us and to have installed itself so securely that it is a question whether it can be dislodged. And yet the way in which we use this term means much for science and for our patients. The meaning of a word, especially such a widely used term as "psychoanalysis," should be clearly and unequivocally understood by all who employ it. This is the apology for briefly discussing this subject.

Freud not only introduced this term but both he and his school have attempted to give it a specific and restricted connotation. They would limit the term "psychoanalysis" to mental analysis according to Freud's method, with his attitude and in accordance with his general conclusions. In this sense the term has a peculiar and artificial meaning. By Freud's method we mean his free association. His attitude (which is based upon his psychology) and his theoretical and practical conclusions include his conceptions of the intimate, individual and psychological significance of the resistance met with in the course of association of ideas, as evidenced in the application of the method of free association; the *a priori* cause to effect relationship which is subsumed to exist between the earlier and later experiences in the life of the individual, with the consequent false interpretation of the associations which present themselves and of coexistent ideas; the conception of rigorous psychical determination in the present life of the individual without regard to the evolutionary or racial history of mankind; the conception of psychical repression, by the endopsychic censor, as the cause for the disappearance from consciousness of all ideas, mental states, or trends not clearly conscious; the far-fetched, highly fantastic and peculiar conception of symbolism; the strange concept of the unconscious; the sexual theories which all lead to a theory of pansexuality with a neglect of the other instincts of man; the reasoning and proof by analogy, coincidence, or coexistence. These and other concepts or attitudes have led to various errors in analysis and interpretation, with the resulting conclusions of the greatest importance to psychopathology, psychiatry, psychology, and to mankind in general. The acceptance of the various dicta have been made by many Freudians a prerequisite for the use of the term "psychoanalysis." In other words it is maintained by them that since Freud first introduced this term it must mean mental analysis in accordance with his ideas. And some even go further and insist that Freud's method of free association must be used. This would thus limit the term psychoanalysis to mental analysis according to the set tenets and dogmas of their school. One must then first adopt the theories of this school *in toto*, before one can practise what they would call psychoanalysis and before one can be labeled a psychoanalyst.

Now, it so happens that psychoanalysis means the same thing as mind or mental analysis. No one will deny that mental analysis has been practised in some form or other by all peoples of the earth since man first came into contact with his fellow beings; in fact, since man first came upon the earth. And psychologists, clergymen, and physicians have been very active in this respect. Surely in recent years, even before the advent of Freudism, mental analyses were not neglected by psychopathologists and psychiatrists. Indeed, the French school paid much attention to the mental study and the mental history of their patients. Janet, Prince, Sidis, and others have surely not neglected mental analysis. It is true that the Freudian movement has given many an added or the needed stimulus in this direction, but we must not forget that analysis of the mental state and the origin and evolution of the mental condition was not new with Freudism. And all such work by others was mental analysis or psychoanalysis, using the latter word in an unrestricted sense to have the meaning which it etymologically should have. As a matter of fact I find certain writers and workers in the field of psychopathology who are not Freudians employing the word "psychoanalysis" as descriptive of their own work. Here they are making use of this convenient and euphonic and etymologically correct word, without any special implications, connotations or restrictions. They are indeed psychoanalysts and are practising psychoanalysis, although not of the Freudian or exclusively Freudian sort. Are they, then, or are they not psychoanalysts? Is or is not their work psychoanalysis? It all depends on what you mean by psychoanalyst and psychoanalysis. If you permit the words to mean what they etymologically do mean, then these men are psychoanalysts and do practise psychoanalysis. But if you have assumed the standpoint of many of the members of the Freudian school and insist on giving this word a special connotation which it etymologically is not entitled to, then these men are not psychoanalysts and do not practice psychoanalysis. Indeed, many of the men of whom I speak would object to being labeled psychoanalysts or of having it said of them that they practise psychoanalysis, since these words have been used by the Freudians and by many others in the narrow sense explained earlier in this paper, and explanations would be in order to signify that they are not full-fledged Freudians or do not subscribe to the Freudian doctrines. Now, there are many differing opinions among the members of the Freudian school itself. Jung, for instance, has come forward with certain criticisms and opposing standpoints. Shall we call Jung, and the others who agree with him as well as others who differ from Freud in one or more point, psychoanalysts, and shall we say of them that they practise psychoanalysis? Surely no one will deny that Jung is a psychoanalyst and that

he practises psychoanalysis. This would be agreed to by all, even the most rigid followers of Freud, in spite of the fact that, with his present views, he is not a full-fledged Freudian. He does, however, adhere to many of the concepts and attitudes of the original Freudian school, as represented, for instance, by Freud himself, and so decidedly differs in many respects from such workers as Sidis, Prince, and Janet, for instance. Jung is not, at present, a true Freudian, but is rather an offshoot of the Freudian school. He has taken more rational and more sensible viewpoints than were adopted by Freud in the field of psychopathology but still differs radically from most other students in this field. Yet his substitution of his theory of regression for Freud's theory of repression and fixation and his modification of Freud's theory of sexuality make him, in many respects, non-Freudian, although still a psychoanalyst. To this, I believe, not even the staunchest adherents of Freud would object. And yet by this very admission they would be agreeing to the employment of the terms psychoanalysis and psychoanalyst in a sense different from that originally conceived by Freud and his school.

Although, as is seen from what has been said above, the limitation and restriction of the words psychoanalyst and psychoanalysis as carried out by the Freudian school are unscientific, narrow-minded, and arbitrary, nevertheless the history of the term would, for a number of years at least, if not for all time, preclude its use in any other sense than that in which it has been employed by the Freudians. So much so has this been the case that to most, if not almost all of those who are at all acquainted with the recent work in psychopathology, the words psychoanalysis and psychoanalyst immediately call up in association the word Freud or Freudian and all that goes therewith. It is thus understood by them that the terms under consideration are used in the narrow, truly Freudian sense. Many of the men who are opponents of the Freudian movement thus immediately and unhesitatingly and emphatically declare that they object to the use of the term psychoanalyst and psychoanalysis in any other sense than that generally accepted and understood. So fixed has this idea become with most of those who are interested in this work that I feel it cannot be done away with. And since the Freudians insist on limiting this term in the way in which I have described and since this definition and understanding of the term has taken such deep root among physicians and others, it seems to me that it would be best to so limit the application of the word psychoanalysis or any of its derivatives. Thus, in spite of the desirability of this word, we must restrict its use as above mentioned. In this way the term is practically dropped from scientific nomenclature. This means that some other, more desirable term must be found to apply to the study of the origin, evolution and history of mental conditions, particularly of an abnormal nature.

The terms *abnormal psychology*, *psychopathology* and *psychiatry* are of old standing but do not refer specifically to the origin, nature and evolution of the mental states under consideration. Psychoanalysis really includes psychogenesis and psychoevolution.

Psychological analysis suggests itself. But there are definite objections to this phrase. To quote Prince[1] on the distinction between psychological and psychical we may say: "A distinction should be made between psychological and psychical, these not being coextensive and always interchangeable terms. Psychological pertains to the empirical data of consciousness (thoughts, ideas, sensations, etc.) while psychical pertains to the inner or ultimate nature of these data. Though the data as given in consciousness are psychical, that which is psychical may not be solely manifested as psychological phenomena. It may be manifested as physical phenomena and perhaps be identified with the energy of the universe. Hence the doctrine of Panpsychism. And so it may be that in its ultimate analysis an unconscious process is psychical (monism) although not psychological and not manifesting itself as a datum of consciousness." Psychological analysis would include the various psychoeducational tests, such as the Binet-Simon tests and their modifications, as well as the various tests for special abilities which have been introduced, as, for example, in studying the immigrant and the juvenile offender.

The writer[2] has suggested the terms "bioanalysis" and "psychobioanalysis." Bioanalysis to many may seem too broad a term, since, in the broad sense, it would include biochemical reactions and similar processes, and, furthermore, it would not lay sufficient stress on the psychic aspect of conduct. Psychobioanalysis would be broad enough and no valid objection to its use could be urged except its length, complexity and its lack of euphony.

Praxiology, the term suggested by Mercier[3] for the science or study of conduct, does not sufficiently bring to our minds the vitalistic and dynamic as opposed to the purely mechanistic and static standpoints.

"Anamnestic analysis," the phrase offered by Haberman,[4] and *psychoanamnesis*, suggested by Taylor,[5] would receive more consideration if we had no better terms.

Sidis[6] has recently introduced the useful term "psychognosis." We shall permit him to tell us in what manner he uses the term. "Psychognosis is not a special method. All I wish to convey by it is what the term means, namely a study, an acquisition of a working knowledge of the patient's soul, so to say." As he further explains, "we must learn to understand not only the patient's physical, nervous, and mental condition, not only his history and the development of his present trouble, but also his personality as a whole, his attitude to his external surroundings, his *Weltanschauung* so to say." And as to the method to be employed Sidis declares: "This can only be accomplished by all methods at our disposal, by hypnoidal and hypnotic states, by examination in the waking state, by constant watching and observation, by drawing out the patient in discussion, and by closely observing him in his actions and behavior in regard to his friends and strangers for a long period of time." Sidis would not exclude the various laboratory tests now employed, although personally he does not approve of them, and considers them cut and dried, clumsy, awkward, and highly misleading. The knowledge thus obtained of the patient's psychic life Sidis regards as psychognosis.

I find psychognosis to be a very valuable and convenient acquisition to our nomenclature. It is, moreover, full of meaning. It is a good substitute for psychoanalysis, and indeed would include information obtained by free association. Although psychoanalysis, as a term, appeals to me more

strongly than does psychognosis, yet, in view of the restricted use of and the ban put upon the term psychoanalysis we should be glad to adopt psychognosis in its stead.

Mental analysis, too, is a good phrase. It might be used to displace any or all of the terms hitherto considered. In fact, under the circumstances, it is the phrase that could be adopted without offense to anybody. Psychognosis, however, is such a fine term that it should not be dropped from scientific nomenclature and may well be generally adopted.

I must repeat that the term psychoanalysis, on account of its connotation and associations, must be dropped from scientific, psychopathological terminology. When used, it should be used in the restricted sense given to it by the Freudian school and others. To this conclusion I am forced, although I have in the past insisted on the broad, unqualified, etymological employment of this word. Mental analysis or psychognosis, preferably the former, are worthy substitutes.

PRINCIPLES OF BROMINE THERAPY IN EPILEPSY.

BY EMANUEL S. BRODSKY, M.D.,

WESTPORT, CONN.

ASSISTANT SUPERINTENDENT OF THE WESTPORT SANITARIUM; FORMERLY ASSISTANT OF THE STATE PSYCHIATRIC INSTITUTION IN THE CANTON OF LUZERNE, SWITZERLAND.

WHEN we question if it is at all useful to treat idiopathic epilepsy, we can say that rational therapy cures a small number and a great number become happier and socially useful. Every neurologist knows there are cases in which epileptics after treatment become free from attacks for several years. We know the epileptic feels subjectively better without the spells than with them, that without the spells he is able to be socially useful and happy, while with them he feels handicapped in life and is therefore emotionally dejected. From our experience we know that rational therapy at least reduces the number of attacks, and consequently they suffer less from the post-epileptic condition. The mental and physical deterioration progresses rapidly when the epileptic is left without treatment and when the seizures become frequent and the period between attacks short. It is known also that each attack places the epileptic in danger not only directly from the mechanical or internal complications, as for instance, suffocation or cerebral hemorrhage, but also from external accidents, such as burning, drowning, etc., which easily occur.

As regards drug treatment we still consider bromides the best, but the treatment with them should be individualized and based upon the following principles: It has been established by experiments that the administration for a long period of equal doses of bromides and alkalies produces an increased retention of the bromine and a simultaneous reduction of the chlorine content in the organism. This retention is the result of insufficient elimination of the bromine ions through the kidneys, which treat the bromine ions and the chlorine ions equally. The volume of the retention depends on the amount of the bromine ions and chlorine ions introduced into our body. The less sodium chloride is administered together with the bromides (especially sodium bromide) the greater is the accumulation of bromine in our organism, and vice versa.

The administration to and the excretion of fluid from the body, our weight, and probably other individual unknown factors promote also this bromine accumulation. The retained bromine remains as bromine ions in the blood serum and tissue fluids, and the osmotic pressure in them remains constant through the elimination of some chlorine ions. These experiments bring to light the antagonism between chlorine and bromine in our body, and establishes the fact that the presence of chlorine ions reduces, and the absence of them increases the effect of bromides. This has brought about the necessity of developing a standardized schedule of dieting in which the amount of salt would be reduced, and has pointed out the principles directing bromide medication in epilepsy.

Toulouse and Richard in 1899, and later Balint, Ulrich, and others, made careful observations and investigations on the salt-free diet. This diet contained only 2 grams of salt per day and did not gain popularity and acceptance. After a certain period the patient refused to follow it because it did not taste good, and the physicians discontinued it because the appetite and nutrition of the patient suffered. The patients showed some symptoms of cachexia and became sensitive to bromides and chlorides, that is, the patient had convulsions when a small increase of sodium chloride in the diet was allowed, or he showed intoxication symptoms when a small amount of bromides was added.

The regulation of the amount of salt in the diet was resorted to. Such a schedule of dieting contained 10-12 grams of salt a day, while the normal content of salt in palatable food contains 20-30 grams. The meals were prepared partially without salt, using it on the table. A combination of sodium bromide, sodium chloride, and extracts of vegetable albumin and condiments, known as Sedobrol, was dissolved in warm or hot water and put on the food to make it palatable and to substitute the necessary bromide medication. For instance, meat was cooked without salt and when served on the table it was covered with the above solution. Potatoes were boiled without salt, sauerkraut was thoroughly washed before cooking, other vegetables were slightly salted, and the bread contained 0.8 to 0.9 per cent. of sodium chloride. Tablets of this preparation made this régime or dieting easy and the treatment of certain cases possible at home.

In the treatment of epilepsy we have to bear in mind that all cases of idiopathic origin represent two groups: (1) Epileptics who are meantally and physically intact and strong; (2) epileptics who are mentally and physically defective and debilitated. In the first group we should start with bromides, 15 grains a day, giving the usual food but eliminating soups or preparing them without salt. Meat,

vegetables, and bread are given as usual with salt. In one, two, or three weeks, depending on the intensity of the case, this dose should be doubled and continued for a long period (several months). Only exceptionally later is it necessary to resort to 3, 4, or 5 grams a day of the bromides. Soups and vegetables can be prepared without salt and made palatable by the addition of Sedobrol. Strong salted foods, such as cheese, ham, and similar things should be avoided.

The treatment in cases of epileptic insanity and demented epileptics included in the second group should be directed quite differently, and cannot be successfully conducted at home. It is a great mistake in such cases to strive to reach a period free from the convulsive seizures. Instead of the suppressed convulsive attacks there appear the so-called status equivalents, excitement and confusion with hallucinations, which are worse than the motor seizures. It is known also that epileptics with confusions and twilight conditions clear up after the convulsive attacks. In such cases one should start with half a gram (8 grains) of bromide salts, continue for several months with this dose and then gradually increasing the dose reach two or three grams a day. When the equivalent symptoms appear one should reduce the dose gradually or give small doses of sodium chloride (2-5 grains or more per day) in the food. All these difficult cases require strict control until a standard is found. When this is found the patient can be treated with a constant dose.

In puberty many epileptics are sensitive to bromides, which warns us at this age to be more careful with the dosing. In all cases bromide therapy must be uninterrupted to reach the best results. The discontinuance of bromides for several days, weeks, or months will spoil the whole course of treatment, the convulsive attacks may appear with a new vigor and not yield to treatment as promptly as before, or even a status epilepticus may be provoked with a fatal ending. There is no strict indication for the discontinuance of bromide medication for a long period. Only in feverish conditions and in difficult bromism should bromide medication be reduced for a certain period or discontinued for more than a few days. Neither the increased number of attacks at the beginning of the bromide medication nor the bromide acne should be a reason for a discontinuance of it. The patient should be prepared for and informed about these points before starting treatment, and the dose of bromide which is empirically established as inhibitory for the convulsions or equivalents ought to be continued for years, as the reduction of the standardized dose causes only disadvantages.

The bromide medication should be started as early as possible. The patient does not usually submit to a systematic treatment when the spells occur only once or twice a year, especially when they are slight. They are usually considered as fainting spells or a consequence of gastrointestinal disturbances. The bromide medication should be applied in small doses when the regularity of the attacks is established as above, and no doubt the epileptic can be made free from attacks for years. The dosage should always be a gradual and prolonged one. It is also wrong to strive for an immediate suppression of the attacks, or to reduce the dose after the patient has been free from seizures for a long period. On the contrary, it is advisable to increase the dose of bromides at the time approaching the seizure.

The amount of sodium chloride has to be gradually reduced, and it is sufficient in all cases to give first the soups without salt, and later to gradually reduce the amount of salt in the vegetables. Reduction of the amount of sodium chloride increases the effect of bromide salts. In cases in which 5 or 6 grams of bromides are not sufficient, which is unusual, and in cases in which attacks occur in the night, one should combine the bromide medication at night with one dose of 0.5 to 1 gram of chloral hydrate. In cases in which a series of convulsions are prone to occur in close succession, it is advisable at the beginning of such series to administer per os or per rectum 1 to 2 grams of chloral hydrate.

In connection with bromide therapy I would like to say a few words about the symptoms and treatment of bromism. French authors speak of the syndrome of cerebrospinal bromism, the symptoms of which are as follows: General delirium, hallucinations, ideas of persecution, violence, ataxia of the limbs and tongue, and disturbance of speech, but these symptoms we do not observe in rational institutional treatment. We observe the following symptoms: The patient becomes indifferent, apathetic, careless in his work, gait and attitude, forgetful and somnolent. Perceptibility is disturbed and the patients are depressed, lacrymose and irritable, but seldom elated. The gait is dragging, the writing is ataxic, the patient cannot find the proper words for expression or proper letters in writing, and the writing may become illegible. The mucous membrane and corneal reflexes are reduced, while the tendon reflexes are increased. The pulse sometimes becomes small, frequent, and irregular. The appetite is poor with constipation or diarrhea, the tongue coated, and a fetor ex ore develops.

The treatment of bromism is very simple. Reduce the amount of bromide salts by 1 to 2 grams per day and increase the amount of salt, or prescribe sodium chloride 1 to 5 grams a day for a few days or weeks. It is surprising how patients with bromism, who are not able to stand, walk, or speak, entirely recover after a few small doses of sodium chloride. The efficiency of this treatment is so pronounced that it is seldom necessary to discontinue the bromide medication for more than a few days. The skin affection in bromism is not coincident with symptoms of the cerebrospinal type, but depends on the skin constitution of the individual. The most frequent of these skin affections is bromide acne, which is treated successfully by arsenic. This should be given in the form of Fowler's solution, 2 to 6 drops twice a day after meals and continued for a long period (weeks or months., and the bromide medication should not be interrupted.

Another affection of the skin, but a rare one, is the bromide ulceration. It is about the size of a silver dollar, flat, with slightly elevated edges consisting of small wart-forming excrescences covered, when neglected, with scabs. This affection is treated with compresses of sodium chloride solution and arsenic internally. A third form of skin affection in bromismus has been described and is also very infrequent. The so-called bromoderma nodosum is similar to erythema nodosum but it is not accompanied by fever and is without pain in the joints. This skin affection is usually located on the legs. They are painful and present, first, deeply circumscribed infiltrated spots, which gradually become superficially seated and more visible, the skin over them becoming red. The treatment is also arsenic.

The bromide stomatitis is treated by a solution of potassium permangate, prescribed as follows:

℞ Potassium permanganate, 1 gram.
Sodium chloride, 50 grams.
Water ad, 1000 grams.

M. S.—One teaspoonful to a glass of water for a mouthwash.

Regarding the bromide preparations, it is known from literature on this subject that sodium, potassium, ammonium, calcium, lithium and strontium bromide have been used with almost the same results. The organic bromide preparations do not have sufficient anti-epileptic effect. Sodium bromide is recommended as the least toxic and is preferred in cases in which the nutrition is poor, especially in women and children. Potassium bromide is the most efficient. Ammonium bromide is preferred when the circulation is weak. Strontium bromide is recommended when gastric disturbances are also present. I have used with good results the pentabromide combination of sodium, potassium, calcium, lithium and ammonium bromide. Only in cases of gastrointestinal torpidity have I been compelled to give either sodium bromide or strontium bromide. Where the heart action is disturbed and digitalis is indicated this has to be properly administered. Not only in Jacksonian epilepsy, but also in cases in which cerebral irritation is suspected trephining after Koche is advisable, leaving a persisting soft fascia-fat covering. The bromide medication should be continued after the operation.

The treatment of epilepsy in all cases should, in the first place, be physical and dietetic. Proper environment, regulation of diet, absolute abstinence from alcohol, proper clothing, sufficient exercise and sleep are important. Hydrotherapy and gymnastics help the metabolic process, and in addition to this appropriate culture of the mind and morals is beneficial. All these measures are best accomplished in an institution conducted on the colony plan or in one conducted especially for this purpose. When institutional treatment is impossible epileptics should always be given some employment, preferably of a physical and congenial nature and out of doors. Diet should be easily digestible, not much water should be taken at meals, but sufficient water should be taken between meals. Food of animal origin, which is likely to generate intestinal poisons and bring on the seizures, should be taken in limited quantities only. More vegetables, fruit, starches, honey and preserves may be given. The correct management of the limitation of the protein intake so as not to exceed the patient's maximum is important. The limitation of protein must be compensated by an increase of the carbohydrate and fatty constituents, and these can generally be taken without limitation.

A HEALTH WEEK IN THE PUBLIC SCHOOLS.

By ADDISON W. BAIRD, M.D.,

NEW YORK.

THE plan I propose aims to devote special time and attention to the subject of health within a period of one week in each school year; so that all school children and their parents will receive clear and definite instruction on matters of hygiene and sanitation.

For school children, a series of a dozen or more fifteen-minute talks on personal hygiene, public sanitation, and prevention of disease may be delivered by physicians or other qualified persons. The topics to be food, milk and water, fresh air, cleanliness, care of the teeth, contagious and communicable diseases, the home, the streets, safety, fire prevention, and kindred subjects; each talk carefully worked out to present the essentials in brief and easily-remembered form. Children are quick to apprehend the central fact; for example, the visiting tuberculosis nurse in a certain district is called "the spit lady." Moreover, children may be appealed to on the side of self-interest. Let a boy be told he cannot become a policeman or a fireman, or join the army or the navy, if he has bad teeth, and he will sit up and take notice. Likewise, a girl will quickly make note of the fact that she is less likely to be popular or to make an advantageous marriage, if she has ill-kept teeth.

For adults, a special stereopticon lecture could be given that would set forth the chief facts of the talks to the children; this lecture to be delivered every night of the week, with cards of admission carried home by the children to their parents. In child welfare work we find that a great many parents are deeply concerned about everything relating to the health and well-being of their little ones. Not only the mothers but the fathers make their interest manifest in various ways. For instance, at a baby contest that was kept going into the early evening, a man came bearing a note he had found at his home: "I have gone to the Baby Show—get your own supper." At first it was thought that he was mad about it; but soon it was found that he had come to meet the other men and to bet on his baby. Whenever there is a fine boy baby in the family the man seems to want to take all the credit to himself.

In conjunction with the day-time talks to children and the evening lecture for adults, there should be a series of panels, or "screens," of the usual type, bearing appropriate pictures, titles, and explanatory legends; these to be displayed in the indoor playground or other suitable space during the whole of the Health Week. There should also be suitable leaflets, or better yet, a primer pamphlet, for free distribution.

In the event that every school cannot have a Health Week every year, it would be desirable to give the course every other year; so that each child would receive this instruction at least three times while passing through the grammar grades. Lectures of a more advanced type might be arranged for high school pupils.

In our own city such a plan might be carried out co-operatively by the following:

Board of Education: Department of Physical Training; Bureau of Lectures.

Department of Health: Division of Child Hygiene; Division of Education and Publicity.

The Life Extension Institute: Educational Bureau; Publicity Department.

Assistance could be had from the Parents' Association in each school, and from neighborhood clubs, settlements, and similar agencies of the vicinity. It might be well to add some arrangements for organizing the children to assist in certain matters of public health and welfare, with an element of competition between classes and schools.

The last week in May of this year there was given in New York City a remarkable demonstration of what can be done by organization and concentration on one health topic. Under direction of Dr. C. Ward Crampton, director of Physical Training in the Public Schools, the week of May 24-29 was made Dental Hygiene Week. In preparation,

special meetings of principals, teachers, and adult high school pupils were held. During the week scores of lectures were delivered to thousands of children by specially trained lecturers, members of the District Dental Societies in the various boroughs of the city; with special talks by principals and teachers in all the schools. The week ended with Dental Hygiene Field Day, which included a competitive drill in Central Park and Van Cortlandt Park by several hundred children, representing Manhattan, Bronx, and Brooklyn. Cooperation was secured through numerous Parents' Associations and mothers' meetings; and several commercial houses contributed great quantities of tooth brushes and tooth powder for demonstration purposes. The press gave much space to Dental Hygiene Week, and by means of moving picture films of Field Day the event has been heralded throughout the country.

The old-fashioned, diffuse way of teaching hygiene in half-hour periods once a week throughout the year, ought to give place to a method whereby the children and their elders will have presented to them with lucid brevity all the information they need on the important topic of health.

PRIMARY MASTOIDITIS.*

REPORT OF TWO CASES.

By CHARLES B. BRODER, A.B., M.D.,
NEW YORK.
VISITING OTOLARYNGOLOGIST, PEOPLES HOSPITAL; ASSISTANT LARYNGOLOGIST, CITY AND POLYCLINIC HOSPITALS AND GOOD SAMARITAN DISPENSARY.

Mastoiditis may be divided into primary and secondary. In primary mastoiditis, as the name implies, the infection begins and involves the mastoid cells. In secondary mastoiditis the infection follows middle ear disease, extension taking place usually through the aditus. A typical form of secondary mastoiditis with the classical signs present is easy of diagnosis. The symptoms pathognomonic of mastoiditis are a congested and bulging membrane with or without a perforation; a profuse thick discharge; drooping of the posterior superior wall of the external auditory canal near the drum; an edematous condition of the mucous membrane of the middle ear; a point of localized tenderness over the antrum tip or point of exit of the emissary vein; external swelling behind the ear; diminution in hearing as shown by watch, acoumeter, conversation and whisper voice, and tuning forks; together with the systemic symptoms indicative of a septic process. An examination of the aural discharge may throw considerable light on the condition. The urgency for operation and the prognosis will vary according as to the type of germ present. With the streptococcus mucosus capsulatus early operation as well as complete exenteration of all cells is advisable.

In atypical secondary mastoiditis with absence of the characteristic symptoms diagnosis may be extremely hard, and the originating point of inflammation difficult to locate. However, careful examination will reveal the mastoiditis to be consecutive to middle ear inflammation. Various anomalous conditions may mask the symptoms. The anterior portion of the mastoid process may be very thick so that there is little, if any, drooping of the posterior superior wall of the external canal. A thickened condition of the tympanic membrane may be sufficient to resist the suppurative process in the tympanic cavity. In fact, cases have come to operation in which middle ear and mastoid disease has been complicated by intracranial and sinus disturbances without the drum membrane ever having ruptured or the ear having discharged. Mastoid abscess also may occur a long time after a suppurating ear has apparently healed and the discharge has ceased. In such cases some infective focus has remained quiescent in the mastoid cells. These atypical cases of mastoiditis are the bane of the otologist. With the absence of all definite signs the disease may extend and produce marked destruction of tissue, symptoms not showing until the inflammation has invaded vital structures, giving rise to labyrinthitis, meningitis, brain abscess or sinus thrombosis, or has progressed outward with the formation of a subperiosteal or a Bezold abscess. In these cases, therefore, early diagnosis is urgent. In primary mastoiditis the inflammation begins in the mastoid bone and may show definite symptoms. It differs therefore from atypical or symptomless mastoiditis in which the infection has proceeded from the middle ear and in which objective signs are wanting.

In my service at the People's Hospital I have lately operated upon two cases of primary mastoiditis.

Case I.—M. B., three months old, seen March 10, 1913, showed a large swelling behind the left ear. The mother stated that the child had received a sharp blow on the left side of the head a week before. The tympanic membrane and the auditory canal were normal in appearance. The case looked like a typical subperiosteal abscess. No history of measles, scarlet fever or diphtheria. No tubercular or specific dyscrasia. Ears all right previous to this trouble. A slight increase in temperature, pulse, and respiration. Blood examination gave a slight leucocystosis with a moderate polynuclear increase. A preliminary paracentesis was negative. On operating, the first incision through the skin and periosteum freed profuse thick pus. There was necrosis of the bone with involvement of the antrum. The entire mastoid cavity was cleaned out and then packed. Healing was rapid. The infection here probably was through the lymphatics, irritation of the periosteum being followed by inflammation with extension and involvement of the bone. The case is of interest as showing the development of mastoid abscess following traumatism, together with the absence of local evidence of middle ear disease.

Case II.—Y. S., seven years old, seen April 13, 1914, presented a left retroauricular bulging. The mother had noticed the swelling for five days previously and could assign no reason for it. A careful examination failed to elicit any connection with the middle ear. There was a very slight haziness of the drum, but the markings were clear, and no congestion or bulging was visible. There was no swelling in the canal wall or any furuncular condition. Functional examination showed some impairment as compared with the other ear. There was a history of frequent attacks of tonsillitis and chorea. On operating a general destructive process was noted, necrosis involving the tip, the zygomatic and perisinus cells. Examination of the mastoid pus showed a coccus with a tendency to form small chains similar to the coccus often noted in tonsillar inflammation. The source of infection here probably was the tonsil, the infective agency passing through without involving the eustachian tube and middle ear into the antrum, in which lodging in a mastoid cell, it is walled off from the tympanic cavity by inflammatory closure of the aditus.

In postauricular cases without local symptoms indicating middle-ear disease careful examination is necessary. Mastoid tenderness and pain may be due to abnormal or functional postaural nerve conditions. Furuncle of the canal is a common cause of swelling of the skin back of the ear. An inflamed

*Read before the Clinical Society of the People's Hospital, May 13, 1914.

condition of the mastoid glands may closely simulate mastoiditis. These anomalous cases demand prompt and exact recognition in order to avert serious consequences, and all aids including transillumination and radiography should be utilized.

221 Second Avenue.

A CASE OF INTENSE FOOD ANAPHYLAXIS.

By LOWELL C. FROST, M.D.,

LOS ANGELES, CAL.

The following case of food anaphylaxis is so typical and clear cut in its symptoms and so intense in its manifestation, as, I believe, to merit presentation. I was called by telephone at 7 P.M., June 2, to see a patient who was reported to be suffering from very acute indigestion. On arriving at the house twenty minutes later I found the condition as follows:

The patient, F. K., a well nourished young woman of about thirty, was in bed in a semi-recumbent posture. The skin over the entire body was bright red with an intense erythema, except the lips and finger nails, which were somewhat cyanotic, and the eyelids, upper and lower, which were bloodless with an edema so marked that it was impossible to open the eyes. The tongue almost filled the mouth, and the patient, although using all the auxiliary muscles of respiration, was able to get very little air into the lungs owing to edema of the glottis, tongue, and nasal mucous membranes. I immediately prepared 2 c.c. of a 1:1000 solution of adrenalin chloride and forcibly injected 1 c.c. into the left nostril, which seemed to be comparatively free, with the intention of allowing it to flow down the nasopharyx to the glottis to relieve the edema at that point. I then injected the remaining 1 c.c. subcutaneously and followed it with a hypodermic of atropine 1/75 grain and morphine 1/6 grain. Meanwhile crushed ice was applied to the throat. The stethoscope at this time showed asthmatic musical high-pitched râles over most of the anterior chest. The heart action was rapid, 104, and of tense quality. The patient felt no better and I was considering tracheotomy, but found that the nasal application of adrenalin had so depleted the edematous membranes of the turbinates that it was now possible to throw a stream of the same solution into the nasopharynx. The edema of the tongue prevented any direct application of the adrenalin to the glottis or any attempt at scarification. The respiration now improved very rapidly and the edema of the eyelids grew less, and in less than thirty minutes after my arrival the condition of the patient was nearly normal except for some erythema, which faded slowly and was gone by the next morning. The bowels had then acted thoroughly as the result of an active catharsis. At that time I gave her general dietetic advice and obtained the following past history and details of the present attack:

Family history: Negative. No trace of asthmatic or gouty diathesis on either side, and no history of any anaphylactic attacks, or reactions against special foodstuffs.

Past history: The patient has been generally healthy. She had measles, mumps, and whooping cough as a child, but with no especial severity. Puberty at thirteen years. Catamenia always normal and regular. She does not remember ever having suffered any attacks similar to that of last night until about one year ago. At that time while walking in the evening, about an hour after supper, she suddenly had a violent paroxysm of sneezing, and this was followed within five minutes by a very marked edema of the eyelids and nasal membranes; at the same time she had a choking sensation and some difficulty in breathing, doubtless due to a similar condition of the glottis and bronchi. At this time she had no erythema, urticaria, or nausea. She had been feeling perfectly well up to the moment of the sneezing, and had eaten a good supper, although she cannot now remember of what it consisted. Three weeks ago she had another attack with the same, although milder, symptoms. This time the paroxysm occurred while she was attending a theatrical performance about two hours after a supper consisting of tea, toast, chops, and blackberries. One week ago she suffered again in the same way, this time about one-half hour after a supper of which strawberry shortcake was the principal part. Recovery was in each of these cases complete and rapid, averaging about three hours, following a self-administered castor oil catharsis and large enemata.

Present illness: The patient had been feeling comparatively well ever since the last attack, and had eaten a supper of toast, tea, milk, ripe strawberries and cream. Immediately after leaving the table she went into the kitchen to help wash the dishes. She had been doing this for not more than five minutes when she suddenly sneezed violently several times in succession. This was accompanied by a rapidly developing edema of the eyelids and nasal membranes, and a feeling of nausea. Emesis followed, the whole supper being rejected. A choking sensation then came on with whistling and difficult breathing, and in this condition I found her, as described above.

One factor in each of the attacks I have not yet mentioned, and it is, I believe, of great importance in the etiology. She did not recall it when first giving me her history, but subsequently remembered that it had been constant at each crisis. This was the fact that for several days before each attack she had passed only small quantities of very dark urine, which burned her during micturition. For the eighteen hours before the last crisis, she had had complete urinary suppression. Questioned as to the daily quantity of water ingested she stated that it was on the average not more than two glasses. Questioned further, she stated that during the previous day she had experienced several rather sharp paroxysms of pain in the lumbar region—a symptom which she had never before felt.

The diagnosis would seem to be anaphylactic reaction to some article of food, probably berries, against which the patient had established an idiosyncrasy, the intensity of the reaction being greatly enhanced by a chronic acidosis of high degree, with acute "acid crises." In the case of each attack the catharsis was profuse, and was followed by great thirst, which led to a markedly increased intake of water. This apparently relieved the acidosis temporarily. The exact relation of acidosis to anaphylaxis has never been fully worked out, but I hope to prove through guinea pig experiments that such a relation exists. Meanwhile I should be glad to obtain through other physicians reports of cases showing this syndrome.

6404 Hollywood Boulevard.

REPORT OF A CASE OF TETANUS WITH RECOVERY.

By JAMES MURPHY, M.D.,

MIDDLETOWN, CONN.

ASSOCIATE MEMBER OF THE MEDICAL STAFF OF THE MIDDLESEX HOSPITAL.

The surgical reports from the armies in the great European War have brought to our attention very conspicuously the treatment of tetanus. The interest in the subject in general and the fact that my patient recovered, which is rare enough in this disease, prompts me to report the following case:

The patient was a man, age 26, in exceptionally good physical condition. On March 17 last he had his right hand caught in the grinder of a grist mill. Upon examination I found the middle finger severed through the second joint and hanging by a tendon, and the ring finger badly lacerated with an open fracture of the second phalanx. I amputated the middle finger through the joint, removed a fragment of bone from the ring finger and applied the usual antiseptic dressing. The wounds seemed to be healing and the patient's condition was good up to March 26. On the afternoon of that day I received word that the muscles of his jaw seemed stiff, I thought immediately of the possibility of tetanus and as the patient lived four or five miles from my office I determined to save as much time as possible and accordingly procured as much antitoxin as I could and lost no time in visiting him. I found him in bed,

temperature 99.4°, pulse 80. The muscles of his jaw were stiff and his neck muscles slightly rigid. The mouth could be opened, but with great difficulty. He complained of pain in his jaw, tongue, and neck, and also of pain in the wounds, which began late the night before, and had kept him awake. I administered 3000 units of antitoxin (all I had) subcutaneously, opened up the wounds and treated them with iodine.

That night the patient was restless, complained of great pain at the site of injection and his temperature went up to 101°. His jaws were more tightly set and the neck muscles more rigid. The following morning I gave him 3000 units subcutaneously and found his condition about the same. March 28 he was admitted to the Middlesex Hospital. At this time his jaws were closed tightly, his neck almost immovable and the spinal muscles were beginning to contract.

Upon examining the fingers at the hospital I found that the wounds did not look healthy, and with the assistance of Drs. Loveland and Walsh I amputated the stump of the middle finger and the whole of the ring finger close to the hand, leaving the flaps open and dressed the stumps with gauze soaked in Harrington's solution. Two hours after admission I began the intramuscular injections of 10 per cent. solution of carbolic acid, 10 minims every two hours, until the urine became smoky in appearance. That evening the patient was given 9000 units intravenously. Temperature on admission 101.4°, pulse 100, respiration 20.

The following day, March 29, the temperature and respiration remained about the same as the day previous. During the day muscular twitching began and continued at intervals of a few minutes. There was no convulsion. The twitching was controlled by bromides, 20 gr., and chloral, 15 gr., p.r.n. At 8 P. M. Dr. Wm. F. Verdi of New Haven was called in consultation and advised an intraspinal injection. Dr. Verdi did the lumbar puncture and injected 6000 units of antitoxin. There was some difficulty in introducing the needle owing to the backward arching of the spinal column.

Four hours after the intraspinal injection the patient became delirious and the temperature went up to 107°. Respirations 40 and irregular, pulse 120. Cold bathing seemed to have a decided effect on the temperature and by 4 A. M. the temperature had dropped to 102°. Pulse 90, respiration 30. For the next twenty-four hours the temperature remained at 103°, remitting slightly after each cold bath. On the fourth day after admission the temperature began to decline and the symptoms began to improve. On April 3 I gave the last dose of antitoxin (1500 units) subcutaneously. April 5 the temperature was normal. April 13 the patient sat up in a chair, and on April 15 he could masticate solid food. He was discharged April 23, cured. In this case the period of incubation was rather long, nine days, which favored the prognosis, and the symptoms developed slowly, another favorable point.

Was this a case which would have recovered without specific treatment? If not, which part of the specific treatment, the antitoxin or the carbolic acid, was effective? Another question: Did the amputation of the fingers have a favorable effect upon the progress of the disease? It is impossible to answer these questions satisfactorily. I am unable to express any opinion as to whether the carbolic acid had any curative influence or not. My patient received 12 gr. before reaching the therapeutic limit, and it was three days after the last dose before the symptoms began to decline. The most favorable comment I can make of Baccelli's method in this case is that it certainly did no harm. The total amount of antitoxin administered was small, 22,500 units, but the first injection was given within a very few hours of the beginning of the symptoms. This circumstance, together with the fact that the symptoms began to improve less than twenty-four hours after the intraspinal injection, leads me to believe that the antitoxin was curative. In another case I would advise a much earlier intraspinal injection and also much larger doses in a vein during the first twenty-four hours.

In regard to amputation, I think that the majority of surgeons are opposed to it on the ground that the shock is more than a patient seriously ill can bear. I think this reasoning applies to major amputations only. It would be obviously poor surgical judgment to subject a patient desperately ill with tetanus to a major amputation unless the operation was clearly indicated for other reasons. In the case of fingers or toes, however, the shock is not great and if our belief that the tetanus bacillus remains localized is true it would seem to be a good prophylactic measure to remove the source of further elaboration of toxins, leaving us to deal only with those already absorbed.

GOUT.

By MAX STRUNSKY, M.D.,

NEW YORK.

For two and a half centuries gout was accepted as a pathological fact. It was recognized to be a disease of common occurrence and was divided into rich man's gout and poor man's gout. Millions of people went to their graves with the belief that they suffered and died of gout. Innumerable physicians became specialists on gout and thousands of volumes were written on the subject. Even to-day one hears of famous and celebrated gout specialists.

For eight years the writer has been working in a hospital for bone and joint diseases where undoubtedly the richest material in this line in New York City is to be seen. He was struck with the fact at one time that of the thousands of cases he has treated he has as yet failed to see a single case which corresponded to that classic syndrome so profusely described in the nomenclature of gout. Inquiry among physicians with extensive experiences with bone and joint diseases and even among those who specialized in metabolism elicited the answer from some that they thought they saw one or two cases of gout in their lives; but in discussing these cases it became evident that they were either of an undetermined infectious origin or belonged to that innumerable class of arthropathies whose causation is yet unknown.

What is to-day was yesterday. Things do not change in this world, it is only our conception of them that changes. If one sees so little of gout now it is fair to assume that there was very little of gout before. On the other hand syphilis is getting to be recognized as a cause of chronic bone and joint diseases more and more. In our hospital, 21 per cent of the total number of cases were found to be due to this cause. Gonorrhea also, especially of the seminal vesicles, is next in its appalling frequency as a cause of bone and joint diseases.

No wonder therefore that the rich man's gout was so prevalent! His indulgence in meat and wine on which the whole trouble was blamed and which was supposed to precipitate an attack is suggestive rather of an infection, for we know that liquor flares up a Neisser infection irrespective whether these cocci make their nest in the urethra or in the articulations of the big toe. Besides people in the habit of indulging need not necessarily have limited their indulgence to the gastronomic. Bone and joint diseases due to syphilis must have existed then as they do now, but the cause lay unrecognized. For the diagnosis can be made only on the *x*-ray findings and the Wassermann reaction, and at that time Roentgen, Hoffmann and Wassermann were either not born yet or were still in knickerbockers.

But what about the poor man's gout? If the excessive consumption of meat and liquor produced gout, how about the poor man who lived on the rich man's estate and who was fed mainly on potatoes, while the one richness in his diet was perhaps the liberal admixture of husk in his bread? To quiet the protestation of reason it was argued that if excessive proteins will cause deposits of uric acid, conversely than an extremely poor protein diet will produce the same result by the law of direct opposites. An hypothesis worthly of a mystic! How much more logical it is to suspect that poor man's gout came into being from the same venereal causes as the rich man's.

Gonorrhea and syphilis, however, were not the only infections that were mistaken for gout. Pyorrhea alveolaris must have contributed legions. For at that time teeth were never cleansed at all, and cavities in the teeth were never filled. Tartar perpetually accumulated at their roots and ate far into their gums, keeping the channels open for infection.

Also flat feet must have added herds of cases, for this pathological entity was as yet unknown. The rich man in pursuit of his pleasure and the poor man from prolonged standing at his labor strained their arches then as they do now, and women by their ultra-fashionable shoes, which fashion decreed upon them in certain periods of history, produced painful feet which were undoubtedly mistaken for gout. That patients with local foot trouble were treated for gout the writer can speak from experience. A typical case is of a woman who came to his office two years ago. She had broken down anterior arches. Hallu valgus, hammer-toes, and bunions were present and the heels were small and undeveloped. Her feet were one mass of pain and they looked infantile, reminding one of the feet of a Chinese woman. All her adult life she wore high heeled, narrow pointed, tight shoes. She said that for twenty years she had been treated for gout.

Deposits of calcium salts are not considered to be a cause of a disease. Undoubtedly the deposit of urates around the joints and in the system has the same function, namely, as a weapon of defence, and is one of the many processes by which repair takes place. What evidence is there to show that deposits of urates around a joint give rise to violent pain and local circulatory disturbance as seen in gout? Gout was never reproduced experimentally on animals by the injection of uric acid, though it was tried many times. Besides, the toxicology of uric acid differs very much from the symptoms of gout. If the presence of tophi means that the individual has gout, and this is the popular conception then every enlargement and swelling of the joints, from Heberden's nodes to spurs, spina ventosa, and even calcified bursæ and degenerated sesamoid bones all help to keep alive the legend of gout.

236 West Seventieth Street.

Articular Grafts. — Roberto Falcone states that a piece of articular cartilage with a thin strip of bone attached is capable of restoring the integrity of a joint if used as a graft. The results are particularly good if the transplantation and the subsequent restoration of the joint surfaces are followed by appropriate physico-mechanical treatment. The best anatomical results are obtained if two grafts are made corresponding to the opposing articular surfaces.—*Riforma Medica.*

Medicolegal Notes.

Oklahoma Medical Practices Act Held Valid.—The Oklahoma Court of Criminal Appeals holds that the Oklahoma medical practices act of 1909 is a valid and constitutional law enacted within the reasonable exercise of the police power of the State, and does not conflict with Section 33 nor Section 57, Article 5, of the Constitution of the State, nor with any provision in the federal Constitution. The title of the act relates primarily to one subject, namely, the practice of medicine, and all its features are cognate to the title as expressed, and go to make up a complete enactment as a complement to the main purpose and intent thereof. Revenue is only an incident to the act, which is not held to be a revenue measure in contemplation of Section 57, Article 5, of the Constitution.

A statute enacted within the reasonable exercise of the police power of the State may impose reasonable fees, and the imposition of such fees in no manner changes such law from a police regulation to a revenue measure. Such fees are not required to be based either upon the cost of the enforcement of the law, or upon the issuance of permits thereunder.—Ex parte Ambler (Okla.), 148 Pac. 1061.

Expert Testimony—Examination Long After Injury.—In an action by a railroad section hand for injuries caused by falling from a hand car no physician who treated the plaintiff at the time of the injury, or near that time, testified, but physicians who examined him at the first trial of the case, which took place about two years after the accident, were called as witnesses. The examination of the physicians showed that at the time of the first trial and since then the plaintiff had suffered from a fistula in ano. There was no dispute in the medical testimony to the effect that a fistula of this kind is caused frequently by tuberculosis, sometimes by piles, but only in very rare instances by traumatic injury. The physicians called by the defendant testified that, in their opinion, it would be impossible for a fistula to result from an accident of this kind, or from any of the injuries indicated by the scars on the plaintiff, which were a scar on his head and another on one of his knees. In such circumstances it was held to be error to allow the plaintiff's medical witnesses to testify that, in their opinion, the fistula was caused by traumatic injury.—Ballard vs. Kansas City, M. & O., Kansas Supreme Court, 148 Pac. 764.

Employment of Physician by Agent of Corporation.—Although as a general rule a corporation is not required to furnish medical attention to an employee injured while engaged in its service, and, nothing else appearing, an agent cannot bind the employer unless it appears that such an authority is within the scope of his agency, yet, where an agent in charge of the business of the employer, although of limited authority, does employ a doctor for an injured employee, and the employer is notified within a reasonable time by the agent that such doctor is in charge of the case, and makes no objection, and it further appears that the agent purchased medicine for the injured man, which was paid for by the employer, this is held to be sufficient evidence to go to the jury of the ratification of the employment.—Roff Oil & Cotton Co. vs. King, Oklahoma Supreme Court, 148 Pac. 90.

Unlawful Dealing in Opium, etc.—The Tennessee act of 1913 prohibiting the sale or distribution of opium or any derivative thereof, except that a physician may prescribe the drugs when in personal attendance on a patient, does not, it is held, deprive a physician of his liberty or property without due process of law as arbitrarily curtailing his right to practise by prescribing according to methods formerly obtaining, but is a valid exercise of the police power to regulate the sale and distribution of dangerous drugs. A detective in the employment of the pure food and drug department of the State procured from a physician a prescription for morphine for an alleged friend, but in fact a fictitious person, and procured a druggist to fill the prescription. It was held that the physician was answerable as aiding in, and hence a principal in, the druggist's offense of a sale in violation of the act. He could not, it was held defend on the ground that the prescription was procured and the sale made for the purposes of a criminal prosecution, or on the theory that the person prescribed for was nonexistent.—Hyde vs. State, Tennessee Supreme Court, 174 S. W. 1127.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

New York, September 18, 1915.

AUTOGENOUS BONE GRAFTS VERSUS LANE'S PLATES.

THE popularity of the Lane plate method of treating fractures of the long bones reached its zenith and began to wane at about the time when the inlay bone graft technique was being developed, and this latter has now become the method of choice with perhaps the majority of American surgeons, particularly in the treatment of ununited fractures.

One of the requisites of success in plating was that the field must be sterile at the outset and must be kept so. In order to secure this condition of absolute asepsis, various refinements in technique were elaborated and insisted upon by Lane, the main points being that, in addition to the usual aseptic precautions such as would be practised by any surgeon, all handling of bone and other subcutaneous structures should be at long range by instruments, all plates, screws, and gauze sponges should be carried to the part desired by long-handled forceps, all hemorrhage should be controlled by clamping, there should be no ligaturing of vessels or suture of muscle or fascia, and under no circumstances should the gloved finger be introduced into the wound. Possibly it is through ultra-rigid adherents to these and other similar details that Lane's own results have been very much better than those of any other operator; hence he is justified in retaining an enthusiasm for the method that cannot be shared by others. It is certainly true that in many instances where fractures have been plated by an experienced operator, equipped with a most complete armamentarium for fracture work and with the help of assistants trained to carry out Lane's instructions to the letter, the immediate result has been good, and yet months afterward evidences of suppuration have appeared and it has been necessary to cut down upon and remove the plate. In these cases the question arises,—Was a low grade infection introduced at the time of operation six months or more previously, or did the presence of a foreign body, causing continued irritation, furnish the *locus minoris resistentiæ* so that blood-borne infection found a suitable nidus and developed months after operation? Whatever the explanation, it is a well-known fact that a great many plates, applied under the most rigid aseptic technique, have had to be removed; and, whether infection came from without or within, the fear that a second operation for the removal of the plate and screws might be required caused this type of operation to decline in favor rapidly as soon as it was found that the transplantation of autogenous bone grafts was equally or more efficacious in obtaining bony union and that secondary operations were rarely necessary.

Since the extravasated blood which always accompanies a fracture furnishes an ideal culture medium, and since even with the most perfect technique it is probable that infection often gains entrance to this area from without or from within, it is self-evident that the method which will be successful in spite of a mild degree of infection will be the method of choice. In this connection the large series of experiments by H. H. Trout and his assistants (*Annals of Surgery*, June, 1915) are of especial significance. In one series of experiments Trout undertook to show the results of small vanadium steel screws in the presence of infection and the behavior of autogenous grafts under similar circumstances. In each instance the wound was intentionally infected and the type of organism (or organisms) producing the infection was determined by culture. Omitting the cases where infection failed to develop or where the animals died from the anesthetic, screws were inserted into the tibia or fibula in infected areas in 27 cases, and in 25 of these the screws sooner or later came to the surface and were removed. In the other two cases the screws remained in position after developing sinuses, both of which finally closed. In determining the fate of an autogenous graft introduced into an infected area, small grafts were taken from each leg and transplanted to the defect in the other. Here again the type of infecting organism was determined by culture. There were 22 animals which survived this operation, thus giving 44 grafts. Five of the bone grafts worked out, while in the remaining 39 the grafts all apparently "took" and were shown by the *x*-ray and later at autopsy to be in place. Thus in these infected cases 92 per cent. of the screws had to be removed and 8 per cent. remained after developing sinuses; while with the autogenous grafts only 11 per cent. were removed and 89 per cent. remained in place. These two series of experiments seem to demonstrate that a foreign body is far more apt to give trouble in the presence of infection than an autogenous graft, and that an autogenous graft will "take" in a large proportion of cases even in the presence of various types of acute and chronic infection.

A second series of experiments was for the purpose of determining the effect of a foreign body placed in the epiphyseal line upon the future growth of that bone in its long axis in comparison with the effect of an autogenous peg under the same circumstances. In ten animals ideal conditions were obtained for determining the effect of the screw—namely, the screw was shown by the *x*-ray to be accurately placed and there was no subsequent evidence of infection. When the animals were killed at the end of six months there was a shortening of the tibia having the screw in four and no ascertainable difference in six. An autogenous spicule of bone was placed in the epiphyseal line of the tibia in a similar manner and under similar conditions in

twelve animals, and at the end of six months no shortening had occurred in any case. Thus with steel screws in the epiphyseal line 40 per cent. showed shortening, while with the autogenous pegs there was no shortening in any case.

It thus seems apparent that in the occasional cases where separation of the epiphysis requires operative treatment, as well as in the operative treatment of fractures where there is a strong possibility of infection, the autogenous bone graft is far more likely to give a perfect result than is the Lane plate.

TOOTHBRUSH TALK.

If it be true that a nation fights on its stomach it can be no less reasonable to believe that a nation fights with its teeth. Toothbrush drills were introduced into the public schools in this country long before military instruction camps were thought of. Both literally and figuratively the teeth have been most efficient weapons of defence from primeval days. The time may come when the United States must show its teeth and, thanks to the worldwide celebrity of American dentists, the demonstration need not be a discreditable one.

Of late the toothbrush has loomed large in the public eye, and while it cannot be deemed that its proper use is an important factor in preventing premature decay of the teeth, nevertheless it is possible that it may be employed too energetically and without good judgment. In their new book on "Alveodental Pyorrhea," C. C. Bass and F. M. Johns, who were among the pioneers in the treatment of the above condition by means of emetine, emphasize the important rôle of trauma to the gum margin involving the peridental membrane. They believe that it is not at all probable that endamebæ can affect the normal or unbroken tissue. The common toothpick and even the vigorous use of dental floss may damage the interdental peridental membrane, and however microscopic the resultant lesions may be, the bruised tissue will doubtless afford a favorable soil for the endameba. The writers above mentioned believe that rough brushing with a stiff toothbrush, especially if performed from side to side instead of from the gums toward the ends of the teeth, favors infection by the endamebæ. Although the bristles of an ordinary toothbrush are simply coarse hairs and appear harmless to the unaided eye, yet under the microscope they resemble coarse nails. Many of them are sharp pointed and can hardly fail to injure the gum. Of course, the softer the toothbrush the less is the damage inflicted, which is also the case if the brush is drawn from above downward in brushing the upper teeth and from below upward in brushing the lower teeth.

The toothbrush is ordinarily used for two purposes: first, to remove or prevent the formation of tartar; and second, to remove food particles from around and between the teeth. The former object, Bass and Johns say, does not justify the heroic brushing to which the teeth are sometimes subjected, and may be accomplished as well by the use of a piece of gauze or cloth. The removal of food is only partly effected by the use of the toothbrush, which even in the most bizarre arrangement of its bristles cannot reach the food particles between the teeth. Dental floss which is generally recommended for this purpose, while it accomplishes its object, tends to inflict an appreciable traumatism by striking the interdental gum with considerable force. The authors quoted above believe that food particles can be removed more effectually by thoroughly rinsing the mouth and forcing water between the teeth several times. But evidently they do not eat corn from the cob.

Not content with this severe arraignment of the toothbrush the above observers bring a sharp indictment against tooth powders and tooth pastes. The gritty material which these invariably contain is said to aid the toothbrush in wounding the delicate epithelial surface of the gums. Evidence of this traumatism is perceived in the pus cells which are found in the secretion removed from the edge of the apparently healthy gum at its attachment to the teeth. Although the enamel of the teeth is so hard as not to be ordinarily injured by repeated polishing with powders or pastes, the necks and roots of the teeth exposed by brushing or pyorrhea, being comparatively soft, cannot resist the grinding action of these agents, which thereby become one of the most patent factors in the causation of dental erosion.

It is doubtful whether any efficient substitute will be found for the toothbrush which has established for itself a firm place among the hygienic necessities of daily life. But the toothbrush might possibly be used more wisely and perhaps less vigorously and less frequently than is now the case. Yet it is well not to throw away even the stiff brush heedlessly. In the Medical Record a short time ago Head of Philadelphia urged the roughest sort of treatment with floss silk and stiff brush for a cure of the very condition which Bass and Johns assert is caused by this means.

ACIDOSIS.

There is a certain impetuous and enthusiastic manner of thinking which we are apt to associate with youth and yet which is temperamental with some of us. We will not speak now of its advantages which are many, but of one disadvantage, not the only one by any means. This is a tendency to seize upon a new theory which seems to explain a group of conditions which have hitherto been obscure and accept it whole-heartedly as the last word on the subject, forgetful of the fact that the ancient roads of medical history are strewn with the bleached bones of theories that were as flourishing in their day as any are now.

One of our present-day theories which has not yet been subjected to the touchstone of time is the explanation that certain, if not all, of the metabolic disorders are due to a toxemia caused by the production of certain toxins in the blood on the order of aceto-acetic acid. To this condition is given the name of acidosis and this title has been joyfully welcomed by that class of clinicians who have a passion for nosology. One aspect of this application of the term acidosis we must keep in mind is its effect upon the lay mind. There is, as every physician

knows, a widespread belief that such disorders as rheumatism and gout are due to an excess of uric acid in the blood and a too uncritical use of the above term by the profession will undoubtedly strengthen this prevalent idea.

In the *Lancet* of July 31, 1915, Benjamin Derham protests against too enthusiastic an acceptance of a diagnosis of acidosis, together with the feeling that when we have thus diagnosed a case we have said all that there is to say upon the subject. Such diagnoses are often based upon nothing more definite than the finding of acetone in the urine. Derham examined a number of cases in his practice and came to the conclusion that acetone probably occurs transitorily in a great many patients, but is not suspected because it is not searched for or if it is the tests are not delicate enough. For example, in the ordinary intestinal indigestion of children following dietetic indiscretions we may find acetonuria and in such a case it appears to be due to an unhealthy and irregular fermentation of the starches and sugars in the intestinal canal. Dr. Derham quotes two illustrative cases.

An acidosis of this kind is, of course, transient and trivial, and the writer says we must guard against using the same term for describing the results of acute gastroenteritis that we apply to a metabolic disorder so profound as diabetes. He gives a number of tests for acetonuria which it is neither practical nor necessary to quote here, but his protest against the indiscriminate use of such a term as acidosis appears to us to be worthy of consideration.

MYOPIA IN SCHOOL CHILDREN.

THE responsibility of the public school as an important factor in increasing the tendency to myopia has long been recognized, but unfortunately few attempts have been made to remove or diminish this source of visual impairment. A step in the right direction has been taken, however, by the appointment in New York of a representative committee, which has considered the various phases of this subject and has recently submitted a report. The committee finds that there are no reliable data upon which to base any estimate as to the extent of myopia among school children in New York City, but holds that educational authorities must take cognizance of the fact that defects of vision are most likely to develop during the school age and must adopt measures to prevent or diminish this impairment.

Attention is called to the fact that all public schools are not equipped with the requisite adjustable desks and seats, and that the adjustable furniture with which the schools are provided is not always properly adjusted. Movable furniture should be provided for the lower grades. The slope of desk tops should be capable of adjustment to the proper angle for writing purposes. Special attention should be paid to the importance of the child bringing the book up toward its eyes, instead of bringing its eyes closer to the book. School lighting may be improved by the use of prisms and other devices. If artificial illumination is employed this should be of the modern semi-indirect pattern. Tungsten lights should, of course, not be used for direct illumination, and all cluster electric illumination should be provided with full frosted globes until replaced by illumination of the semi-indirect type. The question of the proper type of window shade and of its regular and correct adjustment should also be considered. Unnecessary homework should be eliminated. The use of colored crayons for blackboard work should be interdicted except for unusual school work, and blackboards not in use might be covered with light shades.

The above facts are not of mere local interest. They should be carefully weighed by all communities in which there is a public school. Physicians cannot afford to ignore a subject of such vital interest to a large percentage of their patients and they should particularly urge upon parents the need of carefully supervising their children's posture in reading and writing at home.

NEW TESTS OF DEATH.

IT is quite natural that the subject of the speedy and accurate diagnosis of death should receive increasing interest in those countries in which the business of killing seems to have supplanted all other forms of human activity. Three methods of determining the cessation of life are discussed in *La Clinica Medica Italiana*, 1915, No. 3. The first of these is the ether test. A drop of ether is instilled into the conjunctival sac of one eye. If this is followed by a reddening of the conjunctiva it affords proof that the circulation is intact and that life is still present. The other eye is used as a control. The second test has recently been proposed by Icard. It consists in the subcutaneous injection of fluorescin, which, if the individual is still living, is soon followed by a yellowish coloring of the skin and mucosa. The conjunctiva and the mucous membrane of the mouth, and particularly of the frenum of the tongue, show this coloration most distinctly. The test consists in the injection of 8 to 10 c.c. of a solution of 20 grams of fluorescin and 30 grams of sodium carbonate in 100 grams of distilled water. A negative result is obtained in cases of marked slowing or enfeeblement of the circulation, as during the agonal condition. The third test has recently been proposed by Halluin. It consists in direct exploration of the heart by means of a stilette. This is introduced through a small incision in one of the intercostal spaces. Any movement in the heart is communicated to the stilette. In some instances of suspended animation it is possble to arouse cardiac activity by means of gentle movements of the stilette, combined with artificial respiration.

NEGRO PIGMENT AND TROPICAL HEAT.

IT is hardly anywhere disputed that the pigmented skin of the African and other dusky races is an acquired defence against the actinic solar rays, by virtue of which these people can labor in tropical heat and yet escape insolation. The pigment, however, favors absorption of the heat rays and we have therefore to take into consideration the heat regulating mechanism of the body, which makes possible the adaptation of the latter to temperature changes. Before the Royal Imperial Society of Vienna last April (*Berliner klinische Wochenschrift*, June 7) Stigler related some experiments on a negro and a white man who worked in high

degrees of heat. The ergostat was used and the blood pressure, pulse, respiration, and temperature were noted. In the Negro the temperature fell much more rapidly than in the white, and the tests tended to show that the resistance of the negro to heat stagnation is due chiefly to the fact that his cutaneous vessels dilate much more readily and completely, so that more heat is radiated. The pigment, however, serves a useful purpose because it absorbs the yellow heat rays which otherwise would pentrate to the cortex and cause sunstroke. Neither the ultraviolet nor the ultrared rays play any role in the genesis of the latter. The white man in the tropics may become acclimated to the heat to some degree in respect both to his heat regulating mechanism and the production of protective pigment, but the process is a gradual one, and not infrequently the man dies before it is complete.

"Superinfection" and Vaccination.

It is well understood that vaccination performed too late, *i.e.* after the incubation period of variola, cannot arrest or abort the latter, and that as a general rule there is no "take." In very rare cases the two eruptions, vaccina and variola, have appeared side by side, and the latter in such cases seems to have run a severe but not fatal course. In the great Leipzig epidemic of variola in 1870, in which 1700 cases were treated at the University Clinic, two or three were of this type. Vaccination had occurred within one week of the first prodromes. If the two viruses are essentially the same we would regard these curiosities as a sort of superinfection. On the other hand, however, something of the same sort has recently been noted in connection with typhoid immunization. We cannot speak of superinfection here, of course, because dead, sterile cultures were used for the purpose. At a meeting of the Leipzig Medical Society last March (*Muenchener medizinische Wochenschrift*, May 18) Buhrdt, who remembered the variola cases in question, quoted Strümpell to the effect that he had recently seen analogous behavior in enteric fever. Immunization efforts, when made well into the incubation period, appeared, so to speak, to sensitize the patient. He assumed that immunization at that late period used up some of the patient's antibodies, so that the fever ran a more severe course.

The Versatile Physician.

It is well understood that the physician must be all things to all men, a second father to the child, an older brother to the young man, a confidential friend to the mature man, and a counsellor to the old man. He must sympathize with some women, bully some, flatter most of them, and tell the truth to a few. As an ambulance surgeon in the city there are times when he must be quick with his feet and hands, as a country doctor he must often be pharmacist and hostler, and there is no trade of which he is not expected to know a little. Fortunately in this country the physician is as a rule consulted for his ability to treat disease, but this does not seem always to obtain in other lands. For instance, in the *British Medical Journal* for July 10 we find the following remarkable advertisement, under the head of "Medical Officers Wanted": "Wanted, two good fox-hunting doctors." What next? Will they be advertising for a good rat-catching doctor for an old country place? Which reminds us that our professional brethren across the sea may perhaps have seen and commented on an advertisement which appeared in one of our standard medical periodicals about a year ago. We do not care to quote it exactly, but the gist of it was that a chronic invalid wished to employ a graduate of a Class A medical college who must give him his whole time and be of a pleasing personality. His duties, reading between the lines, were to be substantially those of a male nurse and paid companion. The salary was to be $25 a month! As this advertisement appeared a number of times before being finally withdrawn we hope for the credit of our profession that the chronic invalid in question was not overrun with applicants.

Eosinophilia in Dermatology.

It has recently been shown that eosinophilia is a marked and constant accompaniment of anaphylactic reactions. M. L. Ravitch and S. A. Steinberg (*Journal of Cutaneous Diseases*, August, 1915) who discuss the significance of eosinophilia in dermatology, state that this phenomenon accompanying infestations is not due to the presence of the body of the parasite alone but may be caused by the injection of an extract of its body. They cite the observation made by Calamida, namely, that such an extract placed in the tissues in a capillary tube, exhibits a positive chemotaxis for eosinophiles. The eosinophilia following infestations occurs several days after the parasite enters the body of the host, showing that apparently a sensitization of the latter is first necessary. Eosinophilia occurs in eczema, particularly of the exudative type, in trichophytoses, mycosis fungoides, herpes zoster, iodo- and bromoderma, pellagra, dermatitis herpetiformis, leprosy, scleroderma, and psoriasis. In a simple case of pityriasis rubra, after the administration of massive doses of quinine, the eosinophile cells increased almost to 24 per cent.; after discontinuance of the quinine these cells decreased to 8 per cent. Ravitch and Steinberg believe with others that there is a close relationship between eosinophilia and the exudative diathesis.

Exclusiveness in Scientific Societies.

The subject of limited membership in a scientific society, summed up in the two words *numerus clausus*, has been accepted generally as a matter about which there could be no difference of opinion. Every organization has of course the right and the privilege to limit its membership, which right and which privilege would seem to be commensurate with the distinction of the individual members. Nevertheless the principle of *numerus clausus*, at any rate so far as it applies to strictly scientific bodies, has recently been called into question. In the presidential address before the American Dermatolgical Association at its recent annual meeting, Sigmund Pollitzer (*The Journal of Cutaneous Diseases*, August, 1915) states that this principle is utterly without reason. The only explanation for its existence, he says, is the attempt of certain men to confer distinction on themselves by voting themselves better than, or at least different from, others. Pollitzer justly characterizes this spirit as un-American, as a type of snobbishness that is unfortunately too common. He believes that numerical exclusiveness has no place in a scientific society, which should open its doors freely to all who have the requisite knowledge and who possess a high standard of honor.

News of the Week.

New York City's Mortality.—The Health Department reports that there were 1,287 deaths, giving a rate of 11.56 per 1,000 persons, during the week ending September 4, as compared with 1,344 deaths and a rate of 12.56 during the corresponding week of last year. The death rate for the first thirty-six weeks of this year was 13.58 per 1,000 of the population against a rate of 14.05 for the corresponding period of 1914, a decrease of .47 of a point.

Typhoid Fever in an Insane Asylum.—On September 8 there were 80 cases of typhoid fever in the Danville, Pa., State Hospital and 16 cases in the borough outside the institution. The outbreak was traced to one of the assistant cooks who had a walking case of typhoid and had continued on duty for three weeks while ill.

Physical Examination of Food Handlers.—The Weekly Bulletin of the New York City Health Department says the examination of persons handling food has been begun in a limited way in the case of soda water fountain attendants and others engaged in similar employments who have voluntarily presented themselves for such examinations. The revised Sanitary Code requires all food handlers to submit to a physical examination when deemed necessary. A beginning has been made in the principal hotel district of New York City, where the food inspectors of the department will enforce this section and require all cooks, waiters, and other food handlers in the hotels and restaurants to undergo examination at the Health Department's Occupational Clinic. In time it is hoped to extend this work to hotels and restaurants throughout the city.

Fight Against Vaccination.—The Anti-Compulsory Vaccination Society of Newark, N. J., has lost its fight against the exclusion of unvaccinated children from the schools, the State Board of Education having decided that children must be vaccinated before they can be admitted to the public schools. The society purposes taking the case to the courts in an appeal against this decision.

Fall in the Berlin Birth Rate.—It is announced that, as might have been expected, there has been a decrease of approximately 25 per cent. in the birth rate of Berlin for July as compared with the rate for July, 1914, the figures being 2,520 births in July, 1915, as against 3,370 in the same months last year. The number of births in Berlin in May, June, and July of the present year was 7,523, as against 10,030 for the corresponding period in 1914.

Cholera in Trieste.—Cholera is reported epidemic in Trieste and the governor of the province is said to have prevented Dr. Constantini, chief health officer of the city, from taking any measures to control the disease, alleging that there are no funds to defray the expense of sanitary work.

Visiting Sanitarians.—A number of members of the American Public Health Association, which met in Rochester last week, have been inspecting the various health activities of this city as guests of the Department of Health and visiting the institutions of the city as guests of the Department of Charities.

Tuberculosis in the Public Schools.—Notice has been given that teachers suffering with open tuberculosis will not be permitted to follow their vocation in the public schools of this city and those who have chronic coughs and colds are required to report, either personally or through their physicians, to the Board of Health or to the Bureau of Public Health Education for certificates before being permitted to continue in the schools. In the reports received from 56 Manhattan schools a clean bill of health was shown. In 200 other schools in Manhattan, however, there were 15 teachers reported as suffering from pulmonary tuberculosis, and 18 teachers affected by chronic colds and coughs.

Thirty-nine Million Bottles of Milk.—During the year ended August 31 the output of milk from the eighteen Nathan Straus stations in New York amounted to 2,175,208 bottles. In addition to this there were 1,441,580 glasses of pasteurized milk served at the stations in the parks and on the recreation piers during the three summer months. This completes the twenty-fourth year of distributing pasteurized milk to the babies of the city and the total number of bottles supplied in that time was 39,000,000, besides 21,500,000 glasses of milk during the summers. All the bottled milk distributed is supplied in nursing bottles with one feeding portion to a bottle and ready for use after being warmed, the size of the bottle and formula varying according to the ages of the babies.

The Population of New York.—According to the recent State census the population of New York City is 5,066,222. This is an increase of 300,661 since the federal census in 1910, distributed through all the boroughs except Manhattan in which there was a decrease of 187,481. The Health Department's estimate, upon which is based the published death rate each week, has been found to be in excess of the actual population by 740,310.

A New Cancer Prize.—The late Dr. Sigaut willed 8,000 francs to the Paris Academy of Medicine to be given as a prize for research work on cancer as the gastrointestinal tract.

A Portuguese Medical Senator.—Dr. J. P. Lobo, a practising physician in Fall River, Mass., has been elected a member of the Portuguese Senate to represent the colony of Goa in India.

Dr. Edward Nelson Tobey of St. Louis was a passenger on the fruit steamer *Marowijne*, which has not been heard from since August 13 and is believed to have been wrecked by a hurricane in the Gulf of Mexico or the Caribbean Sea on that date. Dr. Tobey was one of a medical party sent by the St. Louis University to British Honduras at the beginning of the summer. He was a lecturer in the medical department of the university and an assistant city bacteriologist.

Dr. M. Schaie has resigned as medical director of the Jewish Home for Chronic Invalids and Consumptives of St. Louis and will engage in private practice after October 1 in New York City.

Flies and Diarrheal Disease.—The Bureau of Public Health and Hygiene of the New York Association for Improving the Condition of the Poor has issued a special publication entitled, "Flies and Diarrheal Disease," descriptive of its three months' study in the homes of over a thousand infants in New York City on the relation of flies and diarrheal disease. Special attention has been given such influencing factors as dirt and artificial feeding and their relative importance determined. The report may be obtained by request from Philip S. Platt, superintendent of the Bureau, 105 East Twenty-second street, New York, N. Y.

Charitable Bequests.—By the will of the late Henry Schaefer of Philadelphia the sum of $2,000 is bequeathed to the German Hospital of that city.

By the will of the late Rose Payson of Wilkes-

Barre, Pa., her estate, amounting to $3,000 is, following the death of her husband and of a second beneficiary, bequeathed as an endowment for a hospital for the cure of inebriates.

In the distribution of the estate of the late Enos R. Artman of Philadelphia, the Philadelphia Home for Incurables receives $5,124.15 and the Kensington Dispensary for Tuberculosis $1,000.

By the will of the late August B. Loeb of Philadelphia the sum of $10,000 is bequeathed to the Mathilde Adler Loeb Dispensary of the Jewish Hospital.

Obituary Notes.—Dr. JAMES W. WALLACE, formerly of Greenway, Ark., died at Paducah, Ky., on August 31 at the age of 57 years. He was a graduate of the College of Physicians and Surgeons, St. Louis, in 1893.

Dr. FRANK M. PUTNAM of Gardner, Me., died on September 1 after a long illness. He was born in San Francisco on July 4, 1853, and was graduated from the Dartmouth Medical School in 1878.

Dr. CHARLES E. NICHOLS of Boston died September 2. He was a graduate of the medical department of the University of Vermont in the class of 1868.

Dr. SAMUEL BURT REED of Maynard, Mass., died suddenly at his home in that town on August 30 at the age of 41 years. He was a graduate of the College of Physicians and Surgeons, Boston, in the class of 1911.

Dr. HENRY J. MULLEN of Glancy, Miss., died on August 25 at the age of 60 years.

Dr. HENRY A. JONES of Millen, Ga., died on August 28 after a brief illness at the age of 47 years. He was a graduate of the New York University Medical College in the class of 1892.

Dr. FREDERICK CORNELL SUTPHEN of Bernardsville, N. J., died in the Morristown Memorial Hospital on September 12, at the age of 43 years. He was born in Peapack, N. J., and was graduated from the New York University Medical School in 1888.

Dr. EMIL ERNEST GUENTHER of Newark, N. J., died at his home in Mountain View on September 12, at the age of 61 years. He was a graduate of the New York University Medical College in 1877.

Dr. JAMES G. KINCAID of Pine Park, Ga., died August 25 at the age of 45 years. He was born at Holly Springs and was a graduate of the Georgia Eclectic College, Atlanta, in the class of 1904.

Dr. WILLIAM P. MARSHALL of Oklahoma City died on August 31 at the age of 72 years. He was a graduate of the Ohio Medical University in 1894.

Dr. JOHN H. SWEET, the last of the original Sweet family of "bone-setters" widely known and popular in New England for several generations, died at the home of his son in Newport, R. I., at the age of 65 years. His death was due to peritonitis following an operation for intestinal trouble.

Obituary.

JOHN EVANS SHEPPARD, M.D.

BROOKLYN, NEW YORK.

DR. JOHN E. SHEPPARD died at his country home, Putnam, Conn., on September 13, following a surgical operation. He was born in Greenwich, N. J., in 1859 and was graduated in arts from Haverford College in 1879 and in medicine from the Medical Department of the University of Pennsylvania, in 1882. After an interneship in the Pennsylvania Hospital and a period of study in Munich and Berlin, he began practice in Atlantic City, but removed to Brooklyn in 1889 and devoted himself to otology as a specialty. He was clinical professor of diseases of the ear at the Long Island College and aurist to the hospital, and was also consulting surgeon to the Brooklyn Eye and Ear, Jewish, Methodist Episcopal, and St. Catharine's Hospitals. He was a member of the American Medical Association, of the American Academy of Medicine, the American Laryngological, Rhinological, and Otological Association, the Pathological Society, the New York Otological Society, and the Associated Physicians of Long Island.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

WAR NOTES—EMERGENCY COMMITTEE—DEARTH OF MEDICAL OFFICERS—STAR AND GARTER HOTEL—WELSH MEDICAL SCHOOL—GUY'S PATHOLOGICAL CHAIR—SERBIAN ARMY MEDICAL PHOTOGRAPHS.

LONDON, Aug. 27, 1915.

THE war in some aspect or other enters into almost all our conversations, even on those of a medical nature. It is discussed in our daily papers which assume familiarity with the professional questions concerned. The sanitary conditions at the front are not what they ought to be, for a correspondent writes about the inadequate burial arrangements causing many bodies to be left for long periods unburied and the rags which once covered them hanging on the barbed wire. The pollution of the atmosphere thus arising is perceived by the men who ascribe to it the origin of what they have named the "liquid German fever." Perhaps the bacteriologists will presently decide on its place in the list of maladies. The chart is said to resemble sandfly fever and its four-day period is similar. Another correspondent at the front says the stable fly abounds there and complains that it occasionally makes open air bathing impossible by rendering anyone unable to defend his naked body against the assaults of its swarms. He relates too that in the great famine which prevailed in that country in 1892 and the land was littered with the decaying carcasses of cattle, an unknown form of fever affected nearly all the inhabitants of the district. At that time any connection between the fly and fever was unthought of, but now when in the trenches "one starts at the prick of the stable fly's proboscis, and smells the old reek of decaying flesh in the air," he admits there is some ground for Thomas Atkins' diagnosis. This trench fever produces a rise of temperature seldom exceeding 103° and lasting only about four days, but leaving debility, headache, and other general symptoms for another week. The unsanitary conditions in the trenches give us cause to wonder at the freedom from epidemic disease which has so far marked the campaign. Great credit is due to the constant efforts of the medical officers to prevent infection from some of the numerous toxic germs abounding in the air and in the soil of the encampments. In the latter the danger of tetanus is obvious and may serve as an example, for from an early period it has been the rule to give an injection of serum to every wounded man as soon as possible after the reception of the wound. The damage to tissues and the shock from the bullet wound are of secondary importance to the poison it may carry. If it has

not taken up mud by contact with the soil the soldier's clothing is contaminated with bacilli—not seldom is it thickly coated with mud in traversing which the bullet takes up some and carries it into the deepest part of the wound it inflicts. Many such cases cannot be dressed immediately and when received at the clearing hospital are found to be infected with fly maggots. In some of these, however, it is reported that the wounds were cleaner than in those in which no maggots were found.

The war emergency committee is calling the attention of all practitioners who are not engaged in the naval or military medical service to the great effort which the country is making and the necessity, as they allege, for a further response from the profession. The director-general, army medical department, Sir Alfred Keogh, has authorized this committee to act as his agent in securing more medical officers of military age. The committee has issued a circular to practitioners pointing out that fighting units cannot be complete without medical officers. They appeal personally to those of military age to come forward, to those over age to encourage the enlistment of their younger neighbors. The elder, they say, who helps to release the younger is doing his part as much as he who serves. Arrangements have been made in a number of districts for setting free a proportion of its practitioners for naval and military service and the emergency committee urge those areas which have not so combined to do so at once. Sir Alfred Keogh has addressed a letter to the committee recognizing it as an excellent medium for dealing with the great problem which, he says, now faces the profession, viz., how to supply medical officers for the forces and at the same time protect the civil population. In gladly authorizing the committee to appeal to the profession to secure these ends he declares that, in his opinion, they cannot put the claims of the medical department of the war office too strongly.

The Star and Garter Hotel on Richmond Hill, which originally cost about £80,000, has been purchased for £21,500 for presentation to the Queen as a permanent home for paralyzed and totally disabled soldiers and sailors. In accepting the gift her majesty has expressed her intention to hand it over to the British Red Cross Society in order that it may be devoted to the care of such disabled men as are retired from the service. The Red Cross Society has undertaken to equip and maintain the institution accordingly. The ground floor contains very fine rooms overlooking the Thames Valley and will make wards to be occupied by the absolutely helpless. A series of special exits will permit all the beds to be rapidly taken into the open air in case of fire or other emergency. Each bed will be run on wheels so that a single nurse can take it into the garden. Patients who can walk a little will be placed upstairs, but there will be ample provision of staircases and lifts. The garden is to be converted into a garden village with cottages and bungalows, each containing one good room with four beds. The number of disabled men who can be admitted when the alterations are completed is reckoned to be about 150.

Colonel Ahearne, R.A.M.C., has returned from a trip in Serbia, where he took many photographs illustrating medical work in the Serbian army and show a hospital unit on its way to the front. The scenes have been transferred to cinema films and are now being exhibited. There are about 3000 of them.

F. Hastings, of the Red Cross Society, said in a recent lecture that the manner in which the wounded have been treated in this unhappy war by the R.A.M.C. and the naval medical service was nothing less than miraculous. The head of the German Red Cross was appointed by the emperor and the society was more or less under the war office. The British society was a purely volunteer organization. He had visited both the trenches and the hospitals and found everything that could be done to ameliorate the suffering of the sick and wounded was being done.

Guy's Hospital has received £25,000 bequeathed by the late Sir William Dunn to establish and endow a lectureship on pathology in its medical school. This will be the most liberally endowed lectureship on the subject.

The foundation stone of a new Welsh school of medicine has been laid at Cardiff. This is the result of the gift of £90,000 by Sir William James Thomas.

A joint appeal for training medical women has been issued by Lord Curzon, Mr. Asquith and Mr. Balfour. They say that the war has been a turning point in the position and new openings have appeared in many directions. Increasing numbers of women are studying medicine and the Royal Free Hospital School is doubling its laboratory accommodation to meet their needs; £15,000 has been received for additional buildings, but as much more is required for the purpose.

The death has occurred of Inspector General H. D. Stanistreet, R.N. He qualified at the Dublin College of Surgeons and Apothecaries' Hall in 1861, joined the medical service of the royal navy the following year, and served until his retirement in 1901.

Progress of Medical Science.

2. The Operative Treatment of Fractures. C. L. Scudder.
3. Endocarditis in Children: Its Prophylaxis and Treatment in an Out-Patient Department. R. S. Eustis.
4. Social Problems Involved in the Treatment of Children with Heart Disease, from the Point of View of an Out-Patient Department. C. M. Welsh.
5. Tonsillectomy as a Therapeutic Measure in the Treatment of Chorea and Endocarditis. J. H. Young.

2. The Operative Treatment of Fractures. — C. L. Scudder states that the pendulum has swung away from the traction treatment to the frequent employment of operation in fractures. Improper and unnecessary operations are being done by incompetent men. There is no more difficult operation in surgery to-day than a carefully conducted operation upon a fractured bone. The longer the operation is done after the fracture the harder the technical work will be. Operations upon fractured bone should be done only by surgeons of very considerable general surgical experience. The conditions under which they are done should be surgically ideal. The necessary and special instruments for precision and convenience should be at hand. The nearer to an anatomical reposition of the fragments of the fracture it is possible to come the greater will be the likelihood of securing a good functional result. A primarily early operation is more desirable than a delayed operation. The results of secondary operations are unsatisfactory. There is less likelihood of the nonoperative treatment being successful as age advances. In childhood the operative and nonoperative treatment about equal each

other in good results. The mortality of the operative treatment is a negligible quantity. Many undesirable terminal conditions will be avoided if the operative treatment is appropriately employed.

3. **Treatment of Endocarditis in Children in an Outpatient Department.**—R. S. Eustis concludes that it is possible by means of a special clinic and a full-time social worker to give efficient treatment for early or threatened endocarditis to patients of the outpatient class. According to the estimates in the literature the incidence of endocarditis in the "rheumatic infections" varies from 40 to 80 per cent.; in the author's series so far it is not over 25 per cent., and perhaps less.

4. **Social Problems in Treatment of Heart Disease in Children.**—C. M. Welsh presents the following synopsis of the social-service aspects of heart disease in children: (1) Adequate medical treatment. (a) Ward treatment when necessary; (b) outpatient treatment, patients to be seen always by the same physician. (2) Adequate social treatment based upon medical treatment and following along closely with it. This should include: (a) Consideration of the home environment, both physical and mental; (b) Consideration of the school environment, both physical and mental; (c) consideration of suitable recreation and occupation. (3) Supervision over a long period of time. (4) Vocational guidance and training.

5. **Tonsillectomy in Treatment of Chorea and Endocarditis.**—J. H. Young notes that the occurrence of chorea after tonsillectomy in twelve out of twenty-one cases strongly suggests that removal of the tonsils does not offer the protection against chorea and endocarditis that many have heretofore believed.

3. **A Sign in Latent Syphilis.**—I. W. Voorhees states that, like many other infectious systemic diseases, syphilis very frequently first manifests itself in the mucous membrane of the nose, mouth, and throat. In performing the now very common operation of submucous resection of the nasal septum on known syphilitic subjects the author has frequently been struck by the difficulty in starting the mucoperichondrium when beginning elevation at the line of incision. Is it not possible that this is due to a productive inflammation in the perichondrium and periosteum, which might go on to tertiary destruction of the septum? Whatever the explanation the author has been able in three cases to make a diagnosis of latent syphilis while doing this operation. In each case it was difficult to start the elevation, there was more bleeding than should commonly obtain with good technique, the blood seemed darker, and the cartilage and bone both had a rough, uneven feel. This latter point is of great importance, and has induced the author to examine with the finger all pieces of bone removed by intranasal surgery.

4. **Treatment of Pruritus.**—W. P. Cunningham notes that the various combinations used in the treatment of pruritus comprise mulls, pastes, salves, powders, and heavy lotions. Thoroughly applied these afford protection from air, moisture, and accidental contacts. That is the secret of success in treating pruritus. That is the explanation of the success of so many different agents in the hands of so many different investigators. It is probable that any nonirritating substance carefully applied would have yielded the same results. The odoriferous element gets the credit, but it was the liberal use of the protecting mass that actually achieved the result. This too explains why hospital cases do better than private cases, and why private patients who are followed up do better than dispensary patients who use their remedies in a slipshod, careless, and incomplete manner. How often has one seen plain olive oil afford relief unobtainable by more elaborate medication! How dependable has one found compound wool-fat ointment made up of nothing but boroglycerin, wool fat and petrolatum! How surprising has been the response to stearate of zinc, which gives an unctuous coating to the supersensitive skin and excludes, air, moisture, and friction! A trial may be made of any of the so-called active agents high in favor among dermatologists, and it will be speedily ascertained that, the menstruum being liberally applied, the results will be entirely different from those of a meager application.

7. **Antityphoid Inoculation of Nurses.**—E. H. Funk believes that antityphoid inoculation among nurses will result in a distinct reduction in the incidence of the disease among them, a reduction which has not been accomplished in the past by instruction in the application of sanitary measures alone. There has been available facts with regard to the source and frequency of contact infection, but one has been unable to reduce the incidence of the disease. The combination of sanitary measures with prophylactic inoculation has seemed to accomplish results not hitherto attained.

9. **Diastolic Pressure.**—L. M. Warfield concludes that the diastolic pressure for any individual is more constant than the systolic. As it measures the peripheral resistance it seems to be a more accurate index of high or low tension than the systolic pressure. The pulse pressure, which represents the actual head of pressure forcing the blood to the periphery, can be obtained only by measuring both the systolic and diastolic pressures. It is therefore of the greatest importance to be able to measure accurately the diastolic pressure. A gradually rising diastolic pressure is of more significance than a high systolic pressure. Large pulse pressures are essential for the compensation of hypertension cases. Decreasing pulse pressures in such cases are a sign of failing heart. Attempts by any means to reduce hypertension without a proportional reduction of the diastolic pressure may be productive of great harm. Any pulse pressure below 30 mm. Hg. must be regarded as low; above 50 mm. Hg., as high. The diastolic pressure should be taken by the auscultatory method at the sudden transition from the loud third tone to the dull fourth tone. In many cases the fifth phase or disappearance of all sound so closely follows the fourth phase that practically the diastolic can be taken at that point. No accurate observation of either systolic or diastolic pressure can be made upon decompensating hearts.

1. Cutaneous Cancer of the Extremities.—H. H. Hazen concludes that carcinoma of the skin of the limbs is not a common affection. The majority of skin cancers arising in these locations are prickle-celled neoplasms, and the majority of these metastasize, some at an early date. Inasmuch as a certain diagnosis can be made only in the early cases by the gross or microscopic appearance, and inasmuch as it is usually deemed unsafe to excise a bit of tissue for examination, it is plain that the proper treatment is to excise the growth *in toto* and make the diagnosis from the entire growth. If it is found to be of a cuboidal or spinal-celled variety the neighboring glands should be removed. The basal-celled growths can be treated by local removal with perfect safety. It is possible that the prognosis in some cases of malignant mole is not absolutely bad if a wide local and glandular operation be done at the onset. Malignant growths always arise from a pre-existing abnormality, so are usually preventable.

2. Salvarsanized Serum in Syphilitic Nervous Disease.—C. E. Riggs believes that every patient with constitutional syphilis, especially in the early stages, should be examined neurologically and serobiologically, and if there be found any symptoms of nervous involvement or an abnormality of the spinal fluid, intraspinal injections of salvarsanized serum should be given until a clinical and laboratory cure is effected. Bernstein advises this procedure as a prophylactic measure in all cases of syphilis, particularly in the primary and secondary stage. Lange's colloidal gold solution is a valuable aid in diagnosis, possessing a marked corroborative value. Paresis gives a characteristic curve (in over 90 per cent. of our cases) so constant, say Grulee and Moody, that "one may venture a diagnosis without other findings, either clinical or laboratory." There is a distinctive tabetic curve which was present in 50 per cent. of the author's cases. The colloidal gold reaction differentiates clearly between paresis and cerebrospinal syphilis. In tuberculous meningitis the colloidal gold solution reacts markedly. Nonsyphilitic cases sometimes give a vague discoloration which may or may not invade the syphilitic zone, but which has no special significance. Intraspinal medication (Swift and Ellis method) is a sane and safe form of therapy, and in the hands of competent men is practically devoid of danger. In cerebrospinal syphilis and tabes, results obtained by conservative workers are most encouraging, and in some cases little less than marvelous. When paresis can be treated in the early, the toxic, stage, before serious regeneration of nervous tissue has ensued, an arrest of the disease may reasonably be expected. Is it too much to hope for a cure?

4. Casein-Milk Feedings. — By W. Gelhorn. (See MEDICAL RECORD, July 3, 1915, page 39.)

10. Intratracheal Ether Anesthesia in Surgery of Brain and Spinal Cord.—C. H. Watt finds that intratracheal ether anesthesia has its greatest field of usefulness in operations on the head, neck, and spinal region. The results in cerebellar cases are the most striking. This method is much safer than the drop ether method; the anesthesia is smoother and is more readily controlled. It also offers the most efficient means of artificial respiration. A review of thirty-five cases of anesthesia by the drop ether method and thirty-five by the intratracheal method shows that the pulse is more regular and less rapid under the latter and that hemorrhage and cyanosis are reduced to a minimum. Although the use of the intratracheal method in the surgery of the brain and spinal cord is becoming more general it has by no means attained the popularity it deserves.

1. A New Theory of Enterostasis. — By A. Keith. (See MEDICAL RECORD, August 7, 1915, page 236.)

2. Gas Gangrene.—A. Fleming points out that there is an increase of growth of the gas-forming organisms by association with the common pyogenic bacteria. This fact is probably of great importance in the incidence of gas gangrene. The presence of the streptococcus aids the *B. aerogenes capsulatus* to establish itself and to produce more rapidly substances which protect the bacillus from the counter attacks of the leucocytes, thus allowing it successfully to storm the defences of the tissues. As regards the treatment of gas gangrene the main essential, both prophylactically and curatively, is free drainage. The progress of the disease is too rapid to allow of any curative vaccine treatment, but it is possible that if a vaccine of *B. aerogenes capsulatus* and streptococcus were injected very early (in exactly the same way as tetanus antitoxin) the temporary increase in immunity to these organisms would be sufficient in most cases, at any rate, to prevent the spread of the infection into the tissues. Large doses of *B. aerogenes capsulatus* vaccine (up to 1,000,000,000) can be injected without any reaction and without the development of any "negative phase"; so it would appear that such a vaccine would be perfectly safe to use.

3. Peritoneal Exudate in Perforation of Stomach and Duodenum.—L. S. Dudgeon and B. C. Maybury refer to the results of their investigation of the bacteriology of the peritoneal exudate in twenty-three cases of perforation of the stomach and duodenum. The list includes eight cases of perforation of the stomach in the immediate vicinity of the pylorus and two elsewhere in the stomach, while there are thirteen instances of duodenal perforation mostly in the first portion. Examination of films of the peritoneal exudate in the above series of twenty-three cases showed an absence of bacteria in thirteen. Of the remaining ten cases cocci represented as diplococci or streptococci were seen in each instance, and bacilli also in two cases which proved to be fatal. The only characters of these streptococci of any special significance are the constant absence of pathogenicity to the lower animals and the absence of hemolytic activity on human red cells.

4. An Atypical Epidemic.—J. T. C. Nash describes a widely spread epidemic chiefly affecting children which was prevalent in Norfolk, England, in the autumn and winter of 1914. The chief characteristic was sore throat not of severe type. Careful consideration of the symptoms indicates that the cases fail to fall in with the required classical characteristics of definite scarlet fever, rubella, glandular fever, or influenza. The last term being applied frequently to protean manifestations may most conveniently be the provisional place of the epidemic in nosology. The subsequent widespread inci-

dence of cerebrospinal fever in England suggests to the author some evolutionary relationship. The author believes that the infection was not evolving so much for influenza as for scarlatina.

7. **A New Sign in Pulmonary Tuberculosis.**—C. Riviere states that in pulmonary tuberculosis characteristic bands of percussion impairment, of constant position, shape, and size are present over both lungs. If any patient the subject of phthisis be placed in the usual attitude for medical examination with muscles relaxed, and by careful gentle percussion each back be examined from below upward, areas of impairment or increased impairment will be found on both sides at certain levels. The lower area extends between the fifth and seventh dorsal spines, or sometimes a centimeter above or below this, and runs out as a peninsula over the scapular region; the upper area lies above the level marked by the intervals between the spines of the first and second dorsal vertebræ. These areas are found to skilled percussion before any other sign of phthisis, in certain cases before symptoms, and persist throughout the course of the disease. On account of their position they are liable when noted to be ascribed wrongly to the presence of tuberculous deposits in upper and lower lobes. They depend, in fact, on no morbid structural changes, but are of reflex origin; though absent in health they can be produced by appropriate means in any normal chest. Their persistent presence denotes an irritation of the lung parenchyma of some causation not necessarily tuberculous. Incidentally they are of notable value in the diagnosis of phthisis. They help to decide the presence or absence of a hidden focus in a case suspected of early tubercle and are useful in the exclusion of all catarrhal conditions not involving the lung parenchyma. Their reflex nature serves to explain the occurrence, unintelligible on other grounds, of percussion impairment in the earliest stages of pulmonary tuberculosis.

Berliner klinische Wochenschrift.

July 26, 1915

Inoculable Fowl Leucemia.—Ellermann of Copenhagen made a preliminary report on this subject last year in which he claimed that the disease is due to a filtrable virus which passes invariably through a Berkefeld filter and variably through a porcelain candle. These criteria serve to isolate the diseae from tuberculosis while at the same time they show a close resemblance to human lucemia in both myeloid and lymphatic forms. During the past year the author has studied especially the hematology of the fowl disease. Normally there should be about 3,000,000 erythrocytes and 30,000 leucocytes per cubic millimeter. The last named comprise mononuclears 65 per cent., polynuclears 35 per cent. Myeloid tissue in addition to its principal occurrence in bone marrow is found in scattered deposits in the liver and kidneys. Lymphatic tissue is also present in these organs in addition to its chief occurrence in the spleen, intestine, thymus, while fowls and nearly related birds also have ordinary lymph nodes. The phenomena of leucemia are intravascular and extravascular. The former include the anemia, the leucocytosis, etc., and the latter the hyperplasia of the lymphatic and myeloid organs. We do not see pure clinical types of disease; for example, in lymphatic leucosis, so-called, we do not as a rule see leucemia, but immense overgrowth of the lymphatic tissue of the liver and spleen. So-called intravascular lymphoid leucosis is characterized by marked accumulation of mononuclears in the capillaries of the liver, spleen, and bone marrow, so that these organs become distinctly enlarged. The blood may be simply anemic or leucemic. The leucocytes of the blood are 90 per cent. lymphocytes. In myeloid leucosis the blood contains 20 per cent myelocytes. The capillaries of the liver, spleen, and bone marrow are distended with mononuclears. In addition to myeloses of organs we also find independent myeloid tumors diffused throughout the body and involving the integument. The disease of fowl leucemia may also manifest itself as a pure anemia.

Treatment of Peroneal Paralysis.—Fleischhauer mentions the great frequency of injuries to the peripheral nerves in the present war. Even when nerve suture has proved successful, months may elapse before the motor power of the nerve returns. Naturally much can be done by prophylaxis, *i.e.* as soon as the injury is received restoration of functional power should never be lost sight of. At the same time we do not know just what amount of good is accomplished by electricity, massage, diathermy, passive motion, etc. While these must not be dropped it is perhaps more rational to support the limb in such manner that the patient can walk and get about on it. Patient should wear a well-fitting laced shoe, and a strap should be so stitched to it that the posture of the foot becomes normal when traction is made upon it. In order to effect this the distal end of the strap is fixed to the inner side of the box toe of the shoe and carried obliquely across the foot and upward along its outer side. The central end of the strap is connected with a suspensory apparatus which consists of circular cuffs above and below the knee and a sling for the shoulder. The strap which connects the shoe with the lower cuff is elastic, and serves to keep the paralyzed foot in pronation. A certain amount of overcorrection is overcome by the action of the calf muscles.

July 27, 1915.

First Cure of Undoubted Kala-azar as a Result of Splenectomy.—Kokoris of Athens reports three cases of splenectomy for kala-azar, the last of which was quite successful. The operation was done in 1912 and the child is still living and well. First done in 1906 the operation has been only regarded as palliative. The patient was five years old when first seen, and his case was the second in the family. The disease had then lasted for over a year. The spleen extended to a finger's breadth of the crest of the ilium, and the liver was also notably enlarged. The Leishman-Donovan corpuscles were discovered in the splenic blood. Blood picture: red cells, 3,658,000, white cells, 2,000, hemoglobin 33 per cent. Splenectomy, with incision in median line followed. The spleen had many adhesions with intestines and omentum, which had to be dealt with by blunt and sharp dissection and ligation. The broad pedicle was tied off in three sections. A bit of the pancreas was accidentally included. The external wound was closed with one plane of sutures. There was marked prolonged postoperative vomiting (forty-eight hours), but the sutures held. There was also a severe postoperative bronchitis with high temperature. The patient otherwise made a good recovery which was necessarily very slow and somewhat interrupted. The liver decreased in size very slowly. At one period the lymph nodes in the axillæ and groins began to enlarge. The child went through variola successfully and ultimately its condition left nothing to be desired. Before 1912 Pappaioannou had reported a case of kala-azar cured by splenectomy, but the spleen had been removed for tuberculosis and Banti's disease, and it was merely an accident that Leishman-Donovan bodies were afterward found in the blood. The merit of the author's work is somewhat disturbed by the fact that cases of kala-azar can recover spontaneously.

Unusual Case of Tetanus.—Happel describes the case of a man with a severe shrapnel wound of the left thigh in which one whole bullet and about fifty fragments had been imbedded and healed in. A first-aid dressing was made. At the regular examination the thigh bone was found badly comminuted, with copious hemorrhage. The wound gave exit to much odorless gas. Fever appeared and a prophylactic injection of antitetanic serum was given. The wound was slit up and numerous fragments of bone removed. Conditions improved, and not until after more than three weeks did tetanus appear. An intensive serum treatment was at once instituted. The wound, which was still suppurating strongly was treated from the viewpoint of a tetanus-infected one. In sixteen days all evidences of tetanus had disappeared. The patient was in excellent shape, save that the thigh fracture had united badly with 7½ cm. shortening. A large fragment of the thigh had independently healed in, causing displacement of both the upper and lower segments. An extension shoe had been made and patient was looking forward to his discharge, nearly four months after his injury, when all at once the scar became red and tender, and fever appeared with a recrudescence of tetanus, over eleven weeks after the disappearance of the first attack. The inflammation about the wound appeared to be an abortive attack of erysipelas. Tetanus pursued a somewhat chronic but nevertheless fatal type, resisting all treatment, and death from exhaustion occurred in twenty-seven days. It was believed at first that some of the shrapnel fragments might have carried germs into the tissues and that these had remained latent for a time. Experiments, however, appeared to show that this view was untenable. More plausible is the view that germs or spores healed into the scar while inactive, had been awakened to virulence by the attack of erysipelas. The protection due to the treatment of the first attack with antitoxin had in the meantime expired.

"Albumin from the Air."—Boruttau candidly admits the shortage of fodder in Germany, which cuts down cattle production, and consequently production of meat and milk. There must be forthcoming more albumin—if not from animals and plants then from other sources—the soil, water, or air. To speak of getting albumin from these sources would be merely a metaphor—what we could get would be nitrogenized matter, not necessarily albuminous. Fifty years ago Pasteur and Ducloux showed that yeast could thrive on an ammonia diet; and in 1907 Ehrlich added that albumin fed to yeast was not utilized until built down to ammonia. In other words yeast cells synthetize ammonia to albumin. As a rule, when we cultivate yeast, it is for the purpose of developing the zymase. The latter is desired because for baking and brewing purposes it splits glucose into alcohol and carbonic acid. The former is drunk (far too much) or used in the arts. The carbon dioxide has a mechanical requirement, viz., to cause bread to "sponge." A little yeast goes in this direction a long way, and a very large surplus remains which is rich in albumin, and at once a potential food for man and fodder for animals. Now we use the *N* of the air to make nitrates and ammonia, and these substances may be fed to the yeast organisms so that the 40 per cent of albumin normal to the latter is derived directly from the air. All that the yeast cells require is a culture medium and a certain temperature, while to get albumin from plants we need weeks of time, a certain soil, favorable weather conditions, and a series of processes—sowing, cultivating, harvesting, etc. In making yeast albumin we take 100 parts glucose and 52 parts of mineral matter containing some nitrogen; this yields 270 parts of compressed yeast, the balance of the *N* coming from the air. This 270 parts give 80 parts of dried substance, and of this 46 per cent. in crude albumin and 29 per cent. carbohydrates. The utilization of the two components is excellent and dogs fed on the "mineral yeast" thrive. The result is pronounced by Boruttau a triumph of the efficiency of German science, technique, and organization, but the proof of the pudding, to man, is in the eating.

Fatalities from Salvarsan.—Fischer adds some new cases to the number already known. These cases should not be straightway set down to arsenical poisoning or to carelessness or defective knowledge on the part of the medical men. In the first case the patient was far gone with tuberculosis with "a foot in the grave." The ravages were extensive. Both adrenal bodies were caseous and this fact alone doomed the patient. While in this desolate condition he contracted syphilis for which he received two salvarsan injections. The latter could hardly have been seriously accused of having caused death. The second case occurred in a young prostitute who contracted syphilis and gonorrhea and received salvarsan. She at once developed anemia and this became pernicious in type. Autopsy showed that the anemia may have been due to persistent loss of blood following abortion. The uterus still contained remnants of a fetus. Syphilis *per se* can also set up severe anemia, so that the two causes may have cooperated in bringing about this end. Salvarsan could hardly be accused in this connection. A third patient, unlike the two first described, showed some evidences of cerebral complication, which pointed to a possible salvarsan death. This opinion was negatived by the results both of lumbar puncture and autopsy. The crux of this case was the fact that patient was a very heavy drinker and this condition forms a contraindication to the use of salvarsan.

Syphilis in Cardiovascular Disease.—H. F. Stoll concludes that syphilis is the underlying or basic factor in a much higher percentage of hypertensive cases than has hitherto been realized. Of fifty individuals studied 90 per cent. either gave a positive Wassermann or luetin test, or were known to have had lues, or had children with hereditary syphilis. Nineteen were from cardiovascular families. In seventeen of them either one or both tests were positive. This strongly suggests the existence of what might be termed "familial cardiovascular syphilis." It would seem that hypertensive disease is one of the most common—possibly the most frequent—of the so-called "late" manifestations of hereditary syphilis. Apoplexy and sudden cardiac death occurring in middle life are almost always due to syphilis, and this cannot be considered a negligible factor even in the aged. The remaining parent and the children of individuals dying a cardiovascular-renal death in middle life should be tested for syphilis, as they are infected in a high percentage of cases. Specific treatment has given very satisfactory results in a few cases, for the most part individuals whose systolic pressure was under 200. The careful administration of mercury over a period of several months has not appeared to be injurious to the kidney even when there was considerable reduction of phthalien output. In a few instances the kidney function was increased several months after treatment. The luetin test, especially if activated by a week of mixed treatment, is often of more value than the most sensitive Wassermann reaction, in detecting these late manifestations of syphilitic infection.—*American Journal of the Medical Sciences.*

Insurance Medicine.

Association of Life Insurance Medical Directors.—The twenty-sixth annual meeting of this association will be held in the board room of the Mutual Life Insurance Company Building, New York, Thursday and Friday, October 14 and 15, 1915.

The first session will be called to order at 10 o'clock sharp on Thursday morning, October 14. The following papers will be read: "Comparative Mortality Experience Among Abstainers and Non-Abstainers from Alcohol"; address by the president, William Evelyn Porter, M.D., medical director, Mutual Life Insurance Company of New York; "Suggestions as to Methods to be Followed in Utilizing the Material Contained in the Report of the Medico-Actuarial Committee," by E. A. Dwight, M.D., medical director, New England Mutual Life Insurance Company; "Symposium Upon the Subject of Gastric and Duodenal Ulcer," (*a*) Medical—By Henry Wireman Cook, M.D., medical director, Northwestern National Life Insurance Company; (*b*) Surgical—By Homer Gage, M.D., medical director, State Mutual Life Insurance Company; (*c*) Roentgenological—By A. H. Busby, M.D., Mutual Life Insurance Company of New York (by invitation); "Conservative Work as Applied to Life Insurance," by Franklin C. Wells, M.D., medical director, Equitable Life Assurance Society; "A Study of 59,270 Exposures of Ordinary Life Insurance Showing Urinary Impairments at the Time of Acceptance," by J. Bergen Ogden, M.D., assistant medical director, Metropolitan Life Insurance Company; "Committee Report on Blood-Pressure Mortality Statistics," by John W. Fisher, M.D., medical director, Northwestern Mutual Life Insurance Company; "Blood-Pressure—with Special Reference to the Diastolic," by Lewis F. Mackenzie, M.D., assistant medical director, Prudential Insurance Company.

The Decreasing Mortality from Tuberculosis.—In his president's address before the Association of Life Insurance Medical Directors at the twenty-fifth annual meeting in October, 1914, Dr. Edward K. Root, medical director, Ætna Life Insurance Company, states that if the medical directors have appreciated their actuaries' lessons and followed their example in the grouping, classification, and study of the lives they, as medical directors, have selected, it must not be forgotten that the unit or individual is still to be dealt with. The human being is of infinite variety in its varied aspects, physical, mental, moral; in its heredity, in its environment. No two men ever go through a case of pneumonia or typhoid fever in precisely the same fashion, nor react to traumatism alike. In spite of the arbitrary classification of men there remains the human equation which is liable to render all calculations naught. Dr. Root believes that there is danger of depending too much on efforts at selection on groups, and subgroups, and statistics, and curves, and calculations, and too little on the personal opinion and professional recommendation of the medical examiner in the selection of the risk. It is the medical examiner who selects the members of the group, and in the final analysis it is the individual that makes up the group, and the death of the individual for which the company has to pay.

This is especially true with reference to risks that have a tuberculous family or personal history. Most clinicians will insist that once tuberculous, always tuberculous; that is, the danger of relapse from an arrested case is greater than the danger of an initial infection. Osler, however, considers that 90 per cent of a population have practically been infected at some time in their lives, yet may never suffer from active signs of the disease. Eighty per cent of all individuals coming to autopsy show some evidences of tuberculosis somewhere in the body, and yet the mortality from tuberculosis in all its forms is steadily decreasing. In 1900 in the registered area of the United States the mortality was 201 per hundred thousand of the population from tuberculous disease of all kinds. In 1912 it was approximately 149 per hundred thousand. This decrease holds good in all civilized lands. In England there has been a decrease of 50 per cent in 40 years.

Among selected lives in life insurance risks, the figures show a marked decrease, although the fluctuations are more violent owing to the smaller numbers included in the group. In 1885 the mortality from tuberculosis in the Ætna Life Insurance Company was 159.9 per hundred thousand; in 1890 it was 80.9 per hundred thousand; in 1895, 82.3 per hundred thousand; in 1900, 115.9. If coincident with the almost universal exposure to the tubercle bacillus goes a falling death rate one of two factors must be responsible for the change. Either the bacillus is losing its virulence, the disease is growing milder, or the race is acquiring a resistance; in other words, becoming immune. No disease has shown so little evidence of apparent immunity conferred by one attack as tuberculosis. Nevertheless, there are certain characteristics of the clinical course of the disease which point toward an acquired resistance, and a consideration of the mortality statistics, both of select lives and of the population at large, is most suggestive that the decreasing mortality as a whole is due to an increasing racial immunity as the most important factor causing this decrease.

Dr. Root quotes from the tables of the Ætna Company showing the decrease in mortality from tuberculosis from 1885 to 1912. A diagram showing in two curves the general death-rate in the United States, and the death-rate from tuberculosis per hundred thousand in the general population of the registration area of the United States is given. These curves each show a similar decrease and the second in some respects parallels the first. In 1900 the Ætna lost 113 per hundred thousand, and in 1912 approximately 78 per hundred thousand.

If immunity can be assumed it explains many interesting results in the mortality tables. If it can be proved, it must be done by the actuary rather than the clinician. It is evident enough whether we assume that immunity is an explanation of the lower mortality from the disease, or whether one or all of the other factors—sanitation, higher standard of living, ventilation, good food—now operative are responsible for the change, but the class of risks we have heretofore regarded as distinctly substandard can be given insurance on far more favorable terms than it was formerly thought possible.

Substitute for Company's Examiner.—A private physician who, in the absence of the regular examiner, examined the applicant for a policy to be issued by an insurance company, is not the agent of the company when he was procured by a friend of the applicant.—Sovereign Camp v. Lillard (Tex.) 174 S. W. 619.

Book Reviews.

HUMAN MOTIVES. By JAMES JACKSON PUTNAM, M.D., Professor Emeritus, Diseases of the Nervous System, Harvard University. Price $1.00. Boston: Little, Brown, and Company, 1915.

OF recent years psychological research has made great progress and we are now beginning to comprehend some of the workings of that part of the human mind termed "the subconscious." The small book "Human Motives," by Professor Putnam, is one of a series of handbooks (The Mind and Health Series, edited by H. Addington Bruce, A.M.) designed to extend knowledge of the important discoveries affecting individual and social welfare that have been made during recent years through psychological research. However, the volume noted does not enter at all deeply into the subject but is mainly intended to focus attention on the aid afforded by modern psychology to the upbuilding of a really sound and practical philosophy of life.

Undoubtedly, it is extremely difficult to delve into the motives of the human mind, but despite handicaps, the individual trained in psychology is able to explain many of these. Dr. Putnam considers the main source of motives the rational basis of religion, the psychoanalytic movement, educational bearings of psychoanalysis, instincts and ideals, and ends by an attempt at synthesis. The chapters dealing with psychoanalysis are especially interesting and instructive, and coming from Dr. Putnam carry the weight of authority.

The entire work will bear careful reading and will undoubtedly repay those who are concerned with psychology and will convince those who have not given the subject their attention that there is more in the matter than they wot of.

THE ORIGIN AND NATURE OF THE EMOTIONS. Miscellaneous Papers. By GEORGE W. CRILE, M.D.; Professor of Surgery, School of Medicine, Western Reserve University; Visiting Surgeon to the Lakeside Hospital, Cleveland. Edited by AMY F. ROWLAND, B.S. Price $3.00. Philadelphia and London: W. B. Saunders Company, 1915.

THE eight papers comprising this volume have appeared in various journals during the past few years, and their subject matter by virtue of its novelty and practical value have attracted considerable attention from medical readers. The Ether Day address on "Phylogenetic Association in Relation to Certain Medical Problems" deals with the already well-known and widely applied doctrine of anociassociation. The biological foundations of this theory are admirably laid down though one may question the zoological nomenclature which would include the turtle and armadillo among the crustaceans. The title of the second paper in this volume is "Phylogenetic Association in Relation to the Emotions." The emotions are regarded as primitive instinctive reactions which represent ancestral acts and utilize the same mechanism as that by which motive acts are performed. The remaining papers deal with the following subjects: "Pain, Laughter, and Crying;" "The Relation between the Physical State of the Brain-Cells and Brain Functions—Experimental and Clinical;" "A Mechanistic View of Psychology;" "A Mechanistic Theory of Disease;" "The Kinetic System;" "Alkalescence, Acidity, Anesthesia—A Theory of Anesthesia." The volume is illustrated with a large number of photographic reproductions. Although the same underlying thought appears in many of these essays, its significance is enlarged and its applications are multiplied. The volume represents a valuable contribution to medical literature.

MATERIA MEDICA AND THERAPEUTICS. A Text-book for Nurses. By LINETTE A. PARKER, B.Sc. (Columbia Univ.), R. N. Bachelor's Diploma in Education, Teachers College; Instructor in Nursing and Health, Teachers College, Columbia University, New York. Illustrated with 29 Engravings and 3 plates. Philadelphia and New York: Lea & Febiger, 1915.

THIS is the latest addition to the "Nurses Text-book Series," and it is one of the best volumes in that series. The author has wisely abstained from including the United States Pharmacopœia with all its preparations, and has made a very judicious selection of such drugs as a nurse may reasonably be expected to know something about. The subject is well handled, and there are many useful diagrams to aid in the explanation of the action of the drugs. The volume is well printed, and is altogether much more attractive than books on Materia Medica are apt to be. Short chapters on Psychotherapy, Hydrotherapy, Electrotherapy, Serums and Vaccines, and Ray Therapy are included. A few of the chemical formulæ are capable of improvement, and one or two of the Latin terms are incorrectly given; but the number of errors is very small indeed, and the book will compare favorably with its competitors.

THE PRINCIPLES OF BACTERIOLOGY, a Practical Manual for Students and Physicians. By A. C. ABBOTT, M.D., Professor of Hygiene and Bacteriology, and Director of the Laboratory of Hygiene, University of Pennsylvania. Ninth Edition, Thoroughly Revised. Price $2.75 net. Philadelphia and New York: Lea & Febiger, 1915.

ANY book which has passed through nine editions occupies a fixed place in medical literature. Abbott's Bacteriology is well and favorably known to a large portion of the medical profession, and its latest edition maintains the high standard of excellence set by the previous ones. It is essentially a book for the beginner which should be supplemented by didactic lectures for the purpose of elaborating obscure subjects. The revision has been a very thorough one, as is always necessary in books on this subject. It is concise and clear with the minimum of theoretical discussion, but marked with a satisfying completeness of detail in the matter of laboratory technique. The illustrations are well chosen and executed.

MODERN MEDICINE. Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by Sir WILLIAM OSLER, Bart., M.D., F.R.S., Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore; Formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institutes of Medicine in McGill University, Montreal, Canada, and THOMAS MCCRAE, M.D., Professor of Medicine in the Jefferson Medical College, Philadelphia; Fellow of the Royal College of Physicians, London; Formerly Associate Professor of Medicine, the Johns Hopkins University, Baltimore. Volume V.—Diseases of the Nervous System—Diseases of the Locomotor System. Second Edition. Thoroughly Revised. Illustrated. Price $5.00. Philadelphia and New York: Lea and Febiger, 1915.

THIS the fifth volume of the second edition of Osler and McCrea's "Modern Medicine" is in every respect fully up to the standard of the former volume. The volume deals with diseases of the nervous system and of the locomotor system.

Chapter 1 is by Dr. Lewellys P. Barber, and is in the form of an introduction to diseases of the nervous system. To diseases of the motor tracts a chapter is devoted, written by Dr. W. G. Spiller. The combined system diseases of the spinal cord is the subject of a chapter contributed by Dr. Colin K. Russel. Scleroses of the brain are dealt with by Dr. Edwin Bramwell, who in alluding to drug treatment of disseminated sclerosis says that he is inclined to believe that arsenic in moderate doses is sometimes of service. Diseases of the meninges are also discussed by Bramwell. The chapter given up to a consideration of diffuse and focal diseases of the spinal cord is by E. Farquhar Buzzard and, as might be expected, is a very clear exposition of the subject. Dr. Joseph Collins discusses the topical diagnosis of diseases of the brain, and likewise considers aphasia at some length. Dr. Harvey Cushing treats of tumors of the brain and meninges and in referring to the pathology of brain tumors points out that one may say that one-half of all brain tumors are gliomas of one kind or another. Cushing also considers hydrocephalus, the text being illustrated by some extremely beautiful plates. Acute encephalitis and brain abscess, diseases of the cerebral blood vessels, diseases of cerebral nerves, diseases of the peripheral nerves, epilepsy, neurasthenia, hysteria, occupation neuroses, paralysis agitans, chorea, myasthenia gravis, astasia-abasia, adiposis dolorosa, syphilitic diseases of the central nervous system, amaurotic family idiocy, arthritis deformans, osteomalacia, and achondroplasia are severally discussed by Drs. E. E. Southard, Henry M. Thomas, E. W. Taylor, Gordon M. Holmes, L. Pierce Clark, Charles W. Burr, Smith Ely Jeliffe, Daniel J. McCarthy, B. Sachs, Thomas McCrae, George Dock and Charles P. Emerson.

The volume is well printed and arranged, adequately illustrated, and provides a valuable reference book on diseases of the nervous and locomotor systems.

THE EARLY DIAGNOSIS OF HEART FAILURE, and Other Essays on the Circulation. By I. STACEY WILSON, M.D. (Edin.), F.R.C.P. (Lond.), B.Sc. (Edin.), Senior Physician, General Hospital, Birmingham, Lecturer on Medicine in the Dental School in the University of Birmingham. With Illustrations. Price $4.50 net. New York: William Wood and Company, 1915.

WORKS concerning the heart in all languages have been very numerous of late years, due to the fact that knowledge regarding that organ has vastly increased within a comparatively short period. Perhaps it might rather be said that knowledge respecting the heart has been revised, amplified, and rendered more accurate. In the acquirement of this knowledge English-speaking writers have been conspicuous, especially Dr. Mackenzie.

The volume before us consists of separate essays dealing mainly with heart failure from the standpoint of early diagnosis. In this direction it covers more or less fresh ground, recognizing types of cardiac failure which are frequently passed over, and indicating certain methods of clinical diagnosis which have received scant mention in the ordinary text books.

The numerous diagrams with which the book is supplied profusely serve to make clear the new theories, the advocacy of new methods, and the dealing with matters not hitherto regarded as of proved clinical importance.

INTERNATIONAL CLINICS. A Quarterly of Illustrated Clinical Lectures and Especially Prepared Original Articles on Treatment, Medicine, etc. Edited by HENRY W. CATTELL, A.M., M.D. Vol. II. Twenty-fifth Series, 1915. Price, $2.00. Philadelphia and London: J. B. Lippincott Company.

IN this issue of the Quarterly there are twenty-three articles on Diagnosis and Treatment, Pediatrics, Medicine and Surgery. Over forty pages are devoted to operations on the nose and throat and the frontal sinuses in articles by Hays and Ballenger. There is a very good article on painful conditions of the foot by Miller, and Eggleston has a brief but comprehensive statement on the "Present Status of Digitalis Therapy." The Quarterly continues to bring to the light subjects of live interest which for the most part are presented in an adequate manner.

THE MEANING OF DREAMS. By ISADOR H. CORIAT, M.D., First Assistant Visiting Physician for the Diseases of the Nervous System, Boston City Hospital, Instructor in Neurology, Tufts Medical School. MIND AND HEALTH SERIES. Edited by H. ADDINGTON BRUCE, A.M. Price, $1. Boston: Little, Brown & Company, 1915.

THIS small volume surveys the principles and results of scientific dream analysis along the lines first formulated by Freud of Vienna. Dr. Coriat, the writer of the book, is by his knowledge of psychology and psychoanalysis, as well as by his familiarity with the views and methods of Freud, peculiarly well fitted for the task he set himself. The work is useful and valuable from many standpoints.

OPERATIVE GYNECOLOGY. By HARRY STURGEON CROSSEN, M.D., F.A.C.S. Associate in Gynecology, Washington University Medical School, and Associate Gynecologist to the Barnes Hospital; Gynecologist to St. Luke's Hospital, Missouri Baptist Sanitarium and St. Louis Mullanphy Hospital; Fellow of the American Gynecological Society and of the American Association of Obstetricians and Gynecologists. Seven Hundred and Seventy Original Illustrations. Price, $7.50. St. Louis: C. V. Mosby Company, 1915.

THE author's intention—stated in the preface—to present "the technique of the various operations, the difficulties likely to be encountered, the indications for operation in the various diseases, and the selection of the exact forms of operative procedure best suited to the particular case, is well carried out. The descriptions of operations are clear, concise, and well illustrated. Essential points are emphasized effectually. The advantages and disadvantages of the several operations are well given. The grouping of these under operations for retrodisplacements is especially satisfactory.

Such operations as curettage of the cervix and specimen excision, which may be performed in one's office, are described with a care for detail which would make them easy of execution by anyone who, as Dr. Crossen puts it, has a "practical working knowledge of the establishment and maintenance of asepsis."

The importance of early diagnosis in malignant disease receives the usual emphasis, and differential methods are given. Though the work is avowedly operative, the parts on differential diagnosis make it of value to the general practitioner by whom most operative cases are first seen. The value of differential diagnosis, checked by operation, shows in many parts, of which the section on chronic pelvic inflammation is an example.

The book will be of distinct value to the young surgeon, in a study of his cases both before and after operation.

MODERN ASPECTS OF THE CIRCULATION IN HEALTH AND DISEASE. BY CARL J. WIGGERS, M.D., Assistant Professor of Physiology in Cornell University Medical College, New York City. Illustrated with 104 engravings. Price, $3.75. Philadelphia and New York: Lea & Febiger, 1915.

DURING recent years our knowledge of the circulation has increased greatly, which of course has vastly aided accurate diagnosis and rendered possible the elucidation of many obscure conditions, the recognition of new diseases, and the institution of new forms of treatment. However, while accurate observation, at the bedside or in the laboratory, is as essential as ever for correct diagnosis, there are many phenomena of the circulation, normal and abnormal, which remain undetected by our unaided senses. Hence the need for and the introduction of various instrumental methods.

In the monograph before us Professor Wiggers has shown how the new methods work. The first section presents the most recent conceptions as to how the circulation is maintained in health. The second section deals with the various instruments and procedures which are available for studying the circulation of man. The third section consists of a correlation of the data obtained by experimental investigation of abnormal conditions in the laboratory, with the results derived from the application of instrumental methods at the bedside and the relation of these, in turn, with the simpler signs and symptoms of the clinic. The entire work is an incorporation of the results of the author's own investigations on the circulation with which have been introduced several unpublished reports of the recent work of a number of colleagues. The book is excellently illustrated and is a valuable compendium of modern views as to the circulation in health and disease.

SOZIALE PATHOLOGIE. Versuch eine Lehre von den sozialen Beziehungen der menschlichen Krankheiten als Grundlage der sozialen Medizin und der sozialen Hygiene von Prof. Dr. med. ALFRED GROTJAHN. Zweite neubearbeitete Auflage. Berlin: Verlag von August Hirschfeld, 1915.

Social pathology is largely a matter of statistics, for in no other way can the social significance of diseases be brought home to the public. Diseases either kill or incapacitate and the more a disease is an enemy to the human race the more data will accumulate and the more there will be to say about it. If deadly diseases like smallpox and hydrophobia require but little space it is because they do not menace many people. To be socially significant a disease must destroy the young and the efficient. *A priori* typhoid fever should require much space, but the mortality from this disease in Germany is but 4 per 100,000 inhabitants, and it does not incapacitate many. The 6 pages given it are ample. At the other extreme 47 pages are devoted to tuberculosis, 18 to venereal diseases, not including 6 pages on blindness, 38 to alcoholism, 9 to epilepsy, etc. If a disease is necessarily fatal in a short time, like cancer and diabetes, it is not followed by any wake of disability, and cancer is preëminently a disease of advanced years, while diabetes attacks chiefly the well-to-do. Nine pages are given to mortality in the first year of life and 5 to suicide, showing the special bearing of these classes of death on social life.

It seems strange to see less than a page devoted to a scourge like influenza, but severe epidemics occur only at long intervals and the direct annual mortality in the healthy is small. The disease increases the death rate among the aged and sickly. Much of its disability is only transitory. Thus in Leipzig 2,828 cases of grip caused a total of over 44,000 days of incapacitation from work. The number of deaths was but 15.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-seventh Annual Meeting, Held at Lakewood, N. J., May 24, 25 and 26, 1915.

THE PRESIDENT, DR. GEORGE N. ACKER OF WASHINGTON, D. C., IN THE CHAIR.

(*Continued from page* 463.)

Allergy to Common Foods.—Dr. OSCAR M. SCHLOSS of New York presented this paper in which he reported his observations derived from a study of 43 cases of food allergy. In this series there were cases of idosyncrasy to milk, egg, beef, horse protein, wheat, rice, and other cereals and food stuffs. It was unusual to find the idiosyncrasy confined to a single food substance, but, as a rule, it was confined to several of those enumerated. Urticaria and angioneurotic edema were among the most frequent symptoms and in the severer types of food idiosyncrasy followed immediately after the ingestion of the toxic food. The relation of eczema to food allergy was of great interest. During the past two and one-half years the writer had observed 18 cases of eczema and in every one there was a cutaneous reaction to the proteins of one or several foods. That the relationship of the foods to the eczema might be causative was attested by the therapeutic results obtained by the withdrawal of the toxic food substance in the cases reported. Cases of asthma provoked by the ingestion of egg were not uncommon, and while asthma might be due to the ingestion of other foods the relationship was far from constant. A third group of symptoms gastroenteric in origin with vomiting, pain, and diarrhea, were probably due to the direct irritant action exerted by these foods. In a fourth group the food idiosyncrasy was indicated by the blood reaction which consisted of eosinophilia. In the more pronounced cases of food indiosyncrasy simple massage of the food protein into the skin caused the appearance of crops of urticarial wheals. Inoculation of the food or protein into a skin abrasion caused the appearance of an urticarial wheal surrounded by a zone of erythema. The reaction was characteristic. Unfortunately a skin reaction was not always present, but in some cases an intracutaneous injection would provoke reaction although the cutaneous test was negative. The cutaneous reaction would often disappear during and directly following toxic food disturbances. Numerous observations in anaphylactic shock had shown that when an animal recovered from the intoxicating dose of protein it then became immune to further injections. This immunity lasted only from one to three months when the animal again became sensitive to the protein. In human beings it had been noted that patients once immunized to egg did not remain immune unless egg in comparatively large amounts was administered continuously. Observation served to show that anaphylactic disturbance might be cyclic even though the food causing the disturbance was ingested continuously. In some instances the idiosyncrasy was inherited while in others it was acquired. The diagnosis of food allergy was made either clinically or by cutaneous reaction. The ideal method of treatment was that of desensitization by the administration of gradually increasing amounts of the toxic protein or by eliminating the offending article from the diet. These two methods might be combined. There were many difficulties encountered in treating eczema and asthma of allergic origin, but the recognition of food allergy as the cause of the condition enabled one to arrive at a rational treatment. His own experience did not warrant the assertion that a satisfactory result could be obtained in all cases in which it was reasonble to suppose the disease was of food origin.

Report of Cases of Various Types of Idiosyncrasy to Milk.—Dr. E. W. SAUNDERS and Dr. T. WISTAR WHITE of St. Louis made this report, which comprised the histories of twelve infants showing idiosyncrasy to milk. From this series the authors summarized as follows: The most serious cases were the exclusively breast fed with a family history pointing to this idiosyncrasy. These cases often proved fatal in the first attack and might elude diagnosis because of the absence of cyclic vomiting. Idiosyncrasy to milk might be shown during the early months of life or might develop at a later period. It might continue through life or it might cease. There might also be a partial idiosyncrasy depending upon the amount and the form of administration of the milk. In conclusion the authors urged individualization in the dietetic treatment of infants and in critical cases of deleterious effects from milk, the recourse to cereal foods in spite of the fear of chronic dystrophies ensuing.

Dr. JOHN HOWLAND of Baltimore stated that Dr. Blackfan had investigated 23 cases of eczema during the last few months and found almost all of them sensitive to one or more proteins. Dr. Blackfan's experience was similar to that of Dr. Schloss. It had been impossible to produce passive immunity. Therapeuticalyl a small number could be definitely helped while a large number could not be improved in any way.

Dr. FRITZ B. TALBOT of Boston said he had been following Dr. Schloss's work and had been making observations of his own. His results had been the same as those of Dr. Schloss. The speaker said he had seen a large number of cases of asthma recently and about 60 per cent. gave a positive skin reaction to some food. He had found that egg was most commonly the offending article and that with egg allergy there was sometimes a positive reaction to nuts, and of these especially to English walnuts. The peanut produced a reaction less frequently than did other varieties of nuts. Many that reacted to egg were also sensitive to horse serum. Those that reacted positively to hen's egg also reacted positively to duck's and turkey's egg. In the majority of cases there was a definite history of intolerance either in the father or the mother or both.

Dr. JOHN LOVETT MORSE of Boston asked Dr. Schloss if he thought every case of eczema and urticaria was due to food allergy.

Dr. TILESTON of New Haven, Conn., said Dr. Schloss's work promised to throw a flood of light on many skin diseases of obscure origin; some had already been shown to be due to anaphylaxis. Aphthous stomatitis and the visceral complications of erythema might be shown to have a similar basis.

Dr. S. MCC. HAMILL of Philadelphia said they were working with this problem and attacking it in a somewhat different way. They were taking children in a condition of moderate ill health with symptoms chiefly referable to the gastrointestinal tract and trying a number of proteids by the puncture test. They used the protein of egg albumen, cow's milk, beef, mutton, fish, etc., to determine for which one an intolerance existed. At present they had a case of asthma which reacted to all the proteins thus far tried but most strikingly to egg albumen. By working back from the history of the case and testing the child's reaction to different proteins one might find some reason for the condition of ill health.

Dr. HAYNES of New York said he had seen several of these cases of food allergy. In one there was an intolerance for egg and chicken above a certain amount; if this limit was transgressed one of two things occurred, either there was a return of the eczema or of asthma, or the child would develop a night cough when it did not get an attack of asthma.

Dr. ROLAND G. FREEMAN of New York said that many children thought to have an idiosyncrasy to milk were taken off milk permanently and injured by not having a well balanced food. He had found it possible acting on the suggestion of Dr. Schloss, to obtain a tolerance to milk in such children by giving a little at first and gradually increasing the amount as tolerance increased. Such children could often eventually take a normal amount of milk.

Dr. GRIFFITH asked if possibly other food constituents might have the same effects as protein, since in some instances a large amount of carbohydrate in the form of sugar had appeared to bear an etiological relation to eczema.

Dr. ISAAC ABT of Chicago said the fact that some foods produced toxic symptoms in certain children showed that there was some peculiarity in the child. At present they had no means of classifying or designating such peculiarities.

Dr. SCHLOSS, in closing the discussion, emphasized the point that it was only in severe cases of food allergy that he had been successful in producing passive sensitization. He would not say that eczema and urticaria were always due to food allergy; they were both diseases of multiple etiology, but of 23 cases of eczema 16 gave a positive reaction to some kind of food. In only a small percentage of cases of asthma did he get a positive indication of food origin. At the time he

made his first report Dr. Schloss said he tested 75 or 80 institutional children as controls and got no reaction. Dr. Talbot in testing 100 children found only two that gave positive reactions and one of these had eczema. When it was found that a child reacted to one type of egg there was usually also a reaction to other types of egg. From his experience it seemed that sensitization could be brought about through the intestinal tract.

Energy Metabolism of a Two-Months-Old Child Fed on Prolonged Protein-Rich Diet.—Dr. RAYMOND HOOBLER of Detroit presented this paper. He stated that the injury, if any, of feeding large quantities of protein to an infant had not been studied to the extent that it deserved. To answer this inquiry the various changes which protein underwent in its transition from an external food product to the cell of the living organism would have to be considered. According to the plan outlined by Dr. Lusk for this investigation it was decided to begin with a low protein diet and determine basal metabolism for this child and then gradually to increase the protein content relatively and actually, maintaining the fat and carbohydrate content as nearly on a level throughout the observation as possible. In all 37 periods of one hour each were studied. The Atwater Benedict calorimeter was used. The results were remarkably uniform and might be summarized as follows: 1. Protein retained for growth caused no increase in metabolism. 2. Protein oxidized caused an increase in metabolism varying with the amount oxidized. 3. The cause of the increased metabolism was the stimulation produced by the aminoacids and their products, derived from protein decomposition. 4. When large quantities of protein were fed along with insufficient carbohydrates and fat, even though ample calories to cover the caloric need might have been given, there was a drain on the fat and carbohydrate stored in the body. Protein food, though greatly in excess, could not be substituted for the need of fat and carbohydrate. 5. The proportion of protein fed as advised and taught was much in excess of the need.

Dr. JOHN HOWLAND said that this work was interesting as showing the effect of high protein content in the food of an infant. In his work along this line he reported four years ago that the protein acted as a stimulant to the general metabolism and while more protein could be consumed, an excess of glycogen was stored up and the injurious effects of other food elements on the organism were more noticeable.

Dr. TALBOT said it was a curious fact that when the protein content of the food was increased, if this increase was in the form of cow's milk, the symptoms of protein excess appeared much sooner than if other forms of protein were added.

Dr. HOOBLER said that in nearly all hours tested the metabolism was low for the first hour and increased with each succeeding hour. There was a lower metabolism for the sleeping hours.

A Further Step in the Adaptation of an Artificial Food to Human Milk.—Dr. H. J. GERSTENBERGER, Dr. H. D. HASKINS, Dr. H. H. MCGREGOR, and Dr. H. O. RUH presented this paper. After describing Friedenthal's milk they stated that they had started out with the idea of making a fat for that milk which would meet the following requirements: First, that it would have approximately the same percentage of low fatty acids as were contained in breast milk; and, second, that it would have approximately the same saponification, Reichert-Meisel iodine number, etc. About that time Dr. Gerstenberger came across the statement of Arnold that a mixture of 86 per cent. lard an 14 per cent. cocoanut oil of certain saponification, Reichert-Meisel and iodine numbers would give a mixture containing the same numbers as were contained in breast-milk fat. Such a fat would float on top of Friedenthal's milk unless homogenized. They then learned of Neuman's method of washing and emulsifying butter. They found, however, that practically no fatty acids were removed by repeated washing of butter with cold water and that an emulsion of the fat could not be obtained when it was added to Friedenthal's milk. Neiman had been able to emulsify his mixture because he had added a large amount of cereal in the form of cornstarch. Washing butter oil with hot water removed but slightly more of the low fatty acids and this amount was so small as to be negligible. It was impossible by the methods which the authors worked out to rid process butter of the rancid odor and make it useful. They later acquired a homogenizer and found that the Friedenthal milk with both cold water washed butter and hot water washed butter could be thoroughly and perfectly homogenized. Most of the infants fed on this milk vomited and had thin, yellow or yellowish stools. The authors then prepared a mixture of lard and cocoanut oil, according to Arnold's suggestion, added this to Friedenthal's milk and found that it was perfectly homogenized. Various combinations of lard, cocoanut oil, codliver oil and cocoa butter were prepared, added to Friedenthal's milk, homogenized and fed to different infants. They had produced a milk which gave the following analysis: Proteid 1.1, sugar 7.07, fat 4.54, salt 0.43. The following points with reference to this study might be emphasized: (1) The giving of an artificial food containing fat of approximately the same qualitative characteristics as breast-milk fat meant a distinct step in advance toward the more complete adaptation of an artificial food to breast milk. (2) This change in the quality of the fat for the artificial food did not apply only to the low fatty acid content of the fat, but also to many of its other characteristics. (3) The homogenizer was a machine that made it possible to suspend such fat in a food that in other respects had been made similar to woman's milk. (4) It represented also a practical means of adding other substances of whatever nature they might be. (5) This scheme made the manufacture of a milk that could be given to young infants as well as to older ones without dilution probable, and this meant, specially if the product could be manufactured at low cost, an accomplishment of great practical importance to both the physician and the family. (6) Manufacture of the food did not present difficulty in keeping the bacterial content extremely low.

Dr. COIT asked Dr. Gerstenberger if he could tell the caloric value of this milk.

Dr. GERSTENBERGER replied that they had calculated the caloric value of this milk in only two proportions. With 4.5 per cent. fat, the caloric content would amount to 770 calories. This could be changed.

Dr. HOOBLER said that in the work recently done in studying the effects of feeding fats, the distinction had been made between the two kinds of fats, those from glandular tissue and those from the non-glandular. To the latter type belonged olive oil, lard tallow, etc. It was found that animals fed on non-glandular fats were not properly nourished. They might appear to be in good condition and might even increase in weight but there must be a further indication of proper nourishment; there must be the capacity for reproduction. Animals fed on non-glandular fats could not produce offspring. With this knowledge it was proper to inquire definitely whether such food as had been suggested would fulfill in every respect the standard that was desirable.

Homogenized Olive Oil and Fat-Free Milk Mixtures in Cases of Difficult Feeding.—Dr. MAYNARD LADD of Boston presented this paper in which he recalled that he had before called attention (paper read before New England Pediatric Society, February, 1915) to the possible application of the principle of homogenization of liquids of different densities to the modified milk mixtures in infant feeding. He had reported the results obtained by replacing cow's milk with olive oil, the emulsion being produced by the homogenizing machine of Gulin of Paris. The chemical composition of the milk was in no wise changed by this process, but the physical condition was so changed that the fat could no longer be separated by the ordinary cream separators. The taste of the milk was decidedly improved by this process, particularly that of pasteurized milk. Homogenized creams could be readily pasteurized. Disturbances of emulsion brought about by rising temperature and transportation were prevented by this process. If all these things were true the process would theoretically yield a more digestible milk mixture. This milk had been used successfully in Fariot's "Gout de Lait" at Belleville. When rennin was added to the homogenized milk the curd resulting was an homogenous flaky paste, resembling closely the curd of human milk. The most interesting application of this principle of homogenization was in connection with the fat constituent of milk modification. It was a question whether it was the fat *per se* which caused the symptom complex known as fat intolerance, or whether it was simply the peculiar quality or reaction of some part of the fat of cow's milk. This question had led him to experiment with vegetable oils and the fats of other animals. It was possible to combine an almost pure olein, palmatin or stearin, with fat-free skimmed milk and so eliminate almost entirely the influence of

the various fats of cow's milk. Dr. Ladd related the histories of several cases in which he had tried olive oil in a fat free lactic acid milk. In two other cases he had used 1.5 olive oil in a malt soup mixture. The results justified the hope that such cases of fat intolerance could be given a food of higher caloric value by this method, with less disturbance of nutrition and greater conservation of strength than by the methods they were now using. Dr. Ladd also reported a number of cases fed on mixtures of olive oil, maltose protein, lime water, and barley starch, in percentages suited to the individual cases in which the results were very satisfactory and which warranted the hope that further investigation would confirm the promise held out by this method of modifying milk.

The Total Non-Nitrogen and the Urea of the Blood, and the Phenolsulphonephthalein Excretion in Infancy and Childhood.—Dr. WILDER TILESTON of New Haven, Conn., presented this report. Using the method of Folin and Dennis, Dr. Tileston found that the total non-protein nitrogen and urea in the blood in childhood was from one-half to two-thirds that of the adult. Using the phenolsulphonephthalein test according to the method of Roundtree and Geraghty for the estimation of kidney function, he found that in this series of children the phenolsulphonephthalein excretion varied from 35 to 64 per cent. for the first hour and from 17 to 41 for the second hour. The average for the two-hour period was from 78 to 81 per cent. This was a higher excretion than was observed in adults. In diseased conditions estimations were made in ten cases of lobar pneumonia. In nine of these it was found that the figures were normal for the total nonprotein nitrogen and urea; in the tenth case there was but a trifling increase. This was contrary to what had been found in adults in whom it had been found to be almost double that found in children. The phenolsulphonephthalein excretion varied from 17 to 85 per cent., with an average of 57 per cent. The case that showed 75 per cent. was not distinctly different from the one that showed 17 per cent.; both had albumin with cast and both recovered. One case of pneumonia that showed a heavy albumin at the height of the disease showed normal non-protein, nitrogen and urea. The albuminuria was only transitory and disappeared with the crisis. In scarlatina they had found no variation in the phenolsulphonephthalein excretion but an increase in the non-protein nitrogen and urea. In five other cases the phenolsulphonephthalein excretion averaged 68 per cent. and the figures for the nitrogen were normal. In summing up the writer said that in general it might be said that non-protein nitrogen and urea showed a less tendency to increase in disease in childhood than in adult life. There was no doubt that it was an important guide in nephritis if there was a high nitrogen percentage, but in the normal individual one could allow for considerable latitude. A rising nitrogen in adults was an indication of some danger of uremia.

Dr. MORSE said that Dr. Hill was making similar tests and his results were the same as those of Dr. Tileston. It would seem from these results that the phthalein test would not prove as useful in children as in adults.

Dr. FREEMAN said that some cases of nephritis passed as much as 90 per cent. of the phenolsulphonephthalein in the first two hours. One child that had come under his observation passed only three per cent. in two hours and yet recovered; such a result rarely occurred in an adult.

Dr. HENRY KOPLIK of New York said that a low degree of phthalein excretion was not inconsistent with recovery. There might be severe nephritis and a quite good phthalein excretion; on the other hand there might be a quite high excretion and the patient not recover. One should make this test before undertaking a surgical operation in children.

Dr. TILESTON said that the phthalein test was only of value at the time it was taken, and did not necessarily indicate whether the patient would succumb or recover.

The Value of the X-Ray in Intra-Thoracic Lesions in Children.—Dr. ROWLAND G. FREEMAN of New York made this presentation. He stated that alone the *x*-ray was generally of little value, but like other evidence, in combination with clinical history and physical signs, it might be conclusive. Auscultation in determining the character of intrathoracic lesions was of materially less value than auscultation in combination with percussion, and auscultation and percussion aided by a good *x*-ray would show lesions in the chest of which one could obtain no knowledge by any of the means of physical diagnosis. The *x*-ray was probably of most value in making the diagnosis of miliary tuberculosis; often it was of value in determining a pneumonia of which one could get no physical signs; and also in making a differential diagnosis between empyema and pneumonia, or in corroborating a diagnosis of diaphragmatic hernia. In lesions of the heart it furnished reliable information as to enlargement modification of the shape of the heart, in dilatation, or the presence of exudate, and it would often differentiate plastic exudate from fluid. The presence of air in the chest was also well shown by the *x*-ray, and if there was a combination of air and pus one got a pus level which was very characteristic. In diseases of the heart in children the *x*-ray gave a most valuable indication of the amount of damage to the heart by the size and shape of the heart shadow and successive pictures provided one of their best means for the control of exercise in these cases. The temperature and pulse rate were of great value, but the *x*-ray would occasionally change their method of treatment to the advantage of the patient. The *x*-ray would show enlargement of the thymus, and of the bronchial and mediastinal lymph nodes and would give corroborative evidence of diaphragmatic hernia. In the diagnosis of obscure case of intrathoracic lesions it should not be neglected. Dr. Freeman illustrated his paper by lantern slides.

Dr. HOWLAND said he could not agree that the *x*-ray showed the enlargement of the thymus gland. It seemed to him that the *x*-ray more often led one into error than it gave assistance in making a diagnosis of enlarged thymus. The *x*-ray might also mislead one with reference to the diagnosis of fluid in the pericardium. Within a certain amount of fluid in the pericardium the pericardial angle became obtuse, but when the pericardium was completely filled with fluid the angle again became acute. So that with a very large amount of fluid in the pericardium one might be led astray by the *x*-ray.

Dr. KOPLIK said one should be very cautious in permitting an *x*-ray to make a diagnosis for him; this was especially true when there was a thickened pleura and a cavity. He had had one case diagnosed thickened pleura when fluid was present. When the *x*-ray picture showed spots it did not necessarily mean miliary tuberculosis. There should be a further comparison of *x*-ray and post-mortem findings before they could rely upon the *x*-ray plate in making a diagnosis.

Dr. DUNN said he wished to agree with what Dr. Koplik had just said. He had had three cases in which the radiologist diagnosed the presence of fluid but in which no fluid was found. They had repeatedly found miliary tuberculosis in cases in which the *x*-ray had failed to show it. They found that the *x*-ray did not agree with the actual findings in one-half the cases.

Dr. HOLT said they had sent the same case to a radiologist on successive days and each day a different diagnosis was made. The *x*-ray was very misleading and was a dubious procedure upon which to base a diagnosis

Dr. GITTINGS said that at the Phipps Institute they had been trying to diagnose alveolar tuberculosis by the *x*-ray; in 50 per cent. the diagnosis based on clinical findings was not corroborated by the roentgenological examination. In 18 bodies studied recently the *x*-ray had failed to differentiate enlarged thymus from enlarged bronchial lymph nodes.

Dr. D. M. COWIE of Ann Arbor, said there were sometimes spots on the flat *x*-ray plate that looked like tubercles and that the flat plate could not be relied upon. If the stereoscopic figure was used the bronchi could be seen in their natural position. The *x*-ray was only an adjunct to be taken in combination with other signs.

Dr. HAND said the *x*-ray was of great value and the more it was used the more it would be appreciated, but they had not laid enough stress on its limitations in diagnosing pneumonia and empyema. In the diagnosis of heart conditions the *x*-ray was of great value. It would show whether there was any hypertrophy of the chambers of the heart.

Dr. FREEMAN said he was not at all surprised at the discussion, in fact, he had brought the slides because he felt that the value of the *x*-ray was not appreciated. These slides showed that there were cases in which the *x*-ray was indispensable in clearing up a diagnosis. It was his own feeling that many physicians expected too much of the *x*-ray. In certain instances it showed

conclusively conditions that other signs failed to indicate.

Transposition of Viscera in an Infant.—Dr. SAMUEL S. ADAMS reported this case, which was attended by his assistant from the time of its birth. He first saw the baby when it was about ten weeks old. There was a complete transposition of the heart and the liver. An examination of the heart revealed all sorts of murmurs. He had seen the baby in April when it was eight months old and it was much better. It had had no attacks of unconsciousness or blueness for some time. The first sound was obliterated. He did not think the foramen ovale would ever close. Dr. Adams exhibited a lantern slide which showed the position of the viscera.

The Composition of Woman's Milk.—Dr. L. EMMETT HOLT of New York presented this communication which gave the result of analyses of 35 specimens of women's milk, 29 individual specimens and 6 composite specimens for 24 hours. The analyses were made for different periods, during lactation and were best understood by the tables.

Periods.	No. of cases.	Fat.	Sugar.	Protein.	Ash.
Colostrum	5	2.83	7.59	2.25	.3077
Transitional ..	6	4.37	7.44	1.56	.2407
Mature	17	3.26	7.50	1.15	.2062
Late	7	2.96	7.45	1.02	.2080

A table was also presented showing the distribution of ash during the different periods. The ash of the colostrum period was high in sodium and potassium chloride. The CaO was almost the same throughout the whole period. For the mature period from the end of the first month to the tenth month the close resemblance in the ratio between proteid and ash in woman's milk and cow's milk was astonishing.

The following table showed the percentage composition of ash per 100 parts of woman's and cow's milk:

	CaO	MgO	P(2)O(5)	Na(2)O	K(2)O	Cl
Woman's..	23.2	3.7	16.5	8.0	28.2	16.6
Cow's....	21.8	2.9	28.9	7.2	26.5	13.0

Dr. GERSTENBERGER asked Dr. Holt if they had made the determination for iron and if they had found that cow's milk had less iron than human milk.

Dr. THOMAS S. SOUTHWORTH said there was an interesting point with reference to the transitional period. This was the time when they were confronted with the bad effects of high fats in the maternal milk and got the gastrointestinal disturbances, and it was interesting to note in the tables that the fats were abnormally high at that time and then there was a tendency for them to fall; in treating these cases if they failed to overcome the difficulty by definite measures, nature came to their assistance by lowering the amount of fat.

Dr. HOLT said that in answer to Dr. Gerstenberger's question, the amount of iron in woman's milk was something like 1.7 milligrams in 1,000 c.c. They had not made this determination themselves because the quantity was so insignificant.

A Plea for Accurate Statistics in Infants' Institutions.—Dr. HENRY DWIGHT CHAPIN of New York presented this paper in which he first stated that the gravity of the problem of mortality in infant's institutions could not be correctly stated. Practically no one knew how many infants passed through these institutions each year, whence they came, or whither they went at the end of their stay. "How many die, how many of those who live, lead lives of suffering and impaired usefulness, and possibly of dependency and crime through the action of causes that might have been prevented—these were the questions for which answers must be sought." The first essential was a knowledge of all the facts, which, at present, were unknown. That the operation of these institutions left much to be desired was known to all who were engaged in the work. This statement was not intended to impugn motives, but to show that the time had come to see if all this energy was expended in the wisest way, and if not, how the methods could be improved. Statistics from the report of the New York State Department of Charities from the period 1909 to 1913 of eleven institutions in the State, in which the death rate for babies under two years of age was based on the total number of children cared for, varied in the different institutions from 183 to 576 per 1,000; while during this same period the death rate of children under two years of age, based on the estimated population of the State, was about one-fifth of that in the institutions. In a recent article the writer reported a study of the mortality in ten infant asylums located in different parts of the United States. The time covered from four to twenty years, taking the longest and the shortest intervals. The rates were based on the ratio between yearly admissions and death rates and varied from 31.7 to 75 per cent. Drs. Holselar and Rude of San Francisco reported a mortality in the foundling asylums of that city of 50 per cent. On boarding out babies with foster mothers in order to secure individual care, the mortality was reduced to 12 per cent. Other statistics were cited by the author which demonstrated beyond a shadow of a doubt that the mortality in these institutions was far higher than it should be; they also served to show that there was no uniform method of collecting data and keeping records, which were exceedingly necessary to show how and where sanitary work must be done and to exhibit the results of sanitary work already under way. In order to secure such knowledge certain specific facts should be given, which in reports accessible to the writer were rarely stated or properly analyzed. All facts that could present a fair picture of the health and hygienic condition of an institution should be carefully presented. Special care should be taken in keeping the records of babies under one year of age. The individual study of each baby should include the history on admission, age, physical condition, length, weight, general nutrition, previous feedings, history, and record of antecedent diseases. The babies should be classified or graded by ages on admission and physical condition, weight, length, and nourishment. Summaries could then be made, showing the average gain or loss under each heading. Comparisons could thus be made with non-institutional babies. There should also be kept a record of diseases acquired during the baby's stay in the institution. Summaries of individual records could then be made showng the number of cases of each disease, of communicable diseases and mixed infection, and these diseases could be classified as to their preventability. The final summaries should show the average age on admission, the average length of stay of those who lived and those who died, together with the total number of admissions and discharges. It would also be of interest to have a proper follow-up system, which could show among other data how many of those infants discharged before reaching the age of one year lived to be one year old.

Dr. HAMILL said he wished to thank Dr. Chapin for presenting this subject to them. Not only was the mortality enormously high and statistical data not definitely standardized, but in some institutions statistics were falsified. He knew of one institution where at a meeting of the Board of Managers it was stated that the mortality rate was 10.8 per cent. He had evidence that this was not correct, since he knew the medical staff in that institution. A physician was only called in when an infant was in a moribund condition, and yet that institution was permitted to exist. The responsibility rested with the medical profession.

Dr. LANGLEY PORTER of San Francisco said that the striking thing in connection with Dr. Rude's work in San Francisco was the reduction of the mortality rate from 65 per cent. to almost nil by a system of boarding out. The infants were carefully followed up by a nurse and a physician and in case of emergency a physician could be procured immediately. The foster mothers became attached to the babies and gave ready compliance to regulations, knowing that if they did not do so the babies would be promptly taken from them.

Dr. SOUTHWORTH said that such statistics as Dr Chapin desired would be very valuable but he did not have much hope that they could be obtained. He knew of one institution, no longer in existence, in which on every admission card was marked "hopeless." That covered all subsequent happenings.

Dr. JOHN MASON KNOX of Baltimore said that among 200 foundlings carefully followed up it was found that between 89 and 90 per cent. died. The 10 per cent. that lived had been taken from the institution for a time. No infant that had remained continuously in the institution lived. Either these institutions should be improved or foster homes should be found for the children. They had no trouble in Baltimore in getting good foster homes.

Dr. HENRY L. K. SHAW of Albany said he was very glad Dr. Chapin had brought this subject before them as he knew of no body of men better adapted to solve the problem than this Society. There were many difficulties and complexities involved in the collection and interpretation of statistics, but he thought that conditions had somewhat improved since Dr. Jacobi had stated that the mortality rate at Randall's Island was

100 per cent. The highest mortality rate was in institutions controlled by religious orders. A certain number of infants had to remain in institutions because of physical defects and because a child had to have certain requirements before it could be boarded out. It was important that they should get at the facts and improve existing conditions.

Dr. CHAPIN, in closing the discussion, said that the president of this society last year had said that it was one of the functions of this society to deal with subjects that touched the public at large and that they must recognize public health questions. One of the most important of these was the problem of infant mortality. While much had been done in the reduction of infant mortality, the thing that was doing more than any other to keep the death rate high was the mortality in institutions and still they allowed such insitutions to exist. The question was what could be done to prevent this high institutional mortality.

Tuesday, May 25—Second Day.

Some Studies on Sugar in Infant Feeding.—Dr. CHARLES HUNTER DUNN of Boston and Dr. LANGLEY PORTER of San Francisco presented this communication which gave the results of feeding high percentages of sugars of different varieties with special reference to urinary findings. In this series of tests there seemed to be no relation between the amount of sugar ingested and the amount excreted in the urine. The ingestion of maltose seemed to result in a greater amount of sugar in the urine than was found when lactose was given. In babies belonging to that class known as difficult feeding cases they had given sugar up to 12 and 14 per cent. and found that all gained in weight, while in some the gain was enormous. They concluded that the danger of sugar intoxication had been greatly exaggerated and that large amounts of sugar could be given in this class of infants with advantage, since the signs of sugar indigestion were easily recognized and could quickly be averted by lowering the amount of sugar.

Dr. SCHLOSS said he had been making investigations with reference to sugar in the urine by all the known methods for the determination of the reduction substances. He found sugar was present in the form of a monosaccharide.

Dr. HOLT pointed out that even though the child gained rapidly with the administration of large amounts of sugar for a short time and then a break came and the gain was lost, no real progress had been made. One of their greatest difficulties was to make children with an intolerance for carbohydrates gain in weight since one could use sugar only in small quantities. The reduction in the sugar content was probably one reason why infants fed on *eiweiss milch* did not gain; the idea that it was because the salts were not furnished, according to present theories, did not hold.

Dr. HENRY KOPLIK expressed the opinion that the sugars should be limited to normal quantities. If large quantities were given, the child gained, then stood still, and then lost. Nothing was gained in the long run by feeding large amounts of sugar.

Dr. GERSTENBERGER asked if the protein content of the food fed these children was also high. With a high protein content a higher percentage of sugar could be given.

Dr. DE WITT H. SHERMAN of Buffalo referred to tests that they had made as to the effects of the different sugars on gastric secretion. Six per cent. dextromaltose, cane, and milk sugars, dissolved in barley water were given. They found that the babies took all the solutions well; that cane sugar stimulated the secretions more than milk sugar; that dextromaltose stimulated the secretions twice as much as milk sugar. It was important to remember this in feeding infants with hypersensitive stomachs.

Dr. GRIFFITH said he had found that infants took from 10 to 13 per cent. of carbohydrates well. It was not a question of temporary gain. They had had better results with this method than with any other.

Dr. DUNN, in closing, said that in his series of cases the gain in weight was retained, fat intolerance might be caused by an excess of sugar or protein fermentation. The amount of protein in the food made a great difference in the sugar tolerance. The sugar should be boiled to avoid the possible bad effects of gas spores or other impurities that might be present. Finkelstein was now using higher percentages of sugar than formerly.

The Indications for Treatment in Severe Diarrhea in Infancy.—Drs. JOHN HOWLAND and W. MCKIM MARRIOTT of Baltimore considered a type of diarrhea which all recognized as particularly serious in infants. It was especially likely to occur in those infants that, as a result of diarrhea, were more or less mal-nourished. After perhaps a few days of mild diarrhea the stools became large, watery, and frequent. The infants were at first restless and sleepless; later it was frequent for stupor to develop, and oftentimes coma. The urine was very scanty and extremely acid, frequently containing albumen and casts, and sometimes sugar. Respiratory symptoms were very often present especially toward the close of the disease. These might consist in a slightly increased ventilation of the lungs or the disturbance might be so great as to amount to severe dyspnea. There was, however, no cyanosis. Post-mortem, the lesions were insignificant. This type of diarrhea had been called "toxicosis" by Czerny and "alimentary intoxication" by Finkelstein. During the past summer, many determinations had been made with reference to the alimentary air. In infants who had severe diarrhea, especially if dyspnea was present, the carbon dioxide tension was found to be very much lower than in health, and the more severe the dyspnea the lower the carbon dioxide tension. It was found also that as improvement took place, the tension rose. As low carbon dioxide tension was one of the evidences of an acidosis, other evidence of this had been sought. The blood serum had been examined by the phenolphthalein test of Sellards and it had been found that in infants with severe diarrhea, a change could be noticed varying from slight diminution in the color to complete absence of color. The hydrogen ion concentration of the serum had also been investigated and had been found to be increased. The urine of these infants had been found very scanty and strongly acid. These infants had a very marked tolerance for alkali, whether given by the mouth, intravenously, or subcutaneously; three, four, or even five times as much alkali had been required to cause an alkaline urine as in health. There was also evidence afforded by the influence of the alkali when given intravenously and subcutaneously. When the alkali had been taken in sufficient amount it had brought about a normal hydrogen ion concentration of the blood, had caused the Sellards test to give a deep purple with phenolphthalein, had stopped dyspnea, and had caused a return of the carbon dioxide tension of the alveolar air to normal, or even abnormally high limits. An examination of the urine for acetone bodies had usually been without result. In view of these findings it seemed perfectly fair to say that these patients suffered from acidosis and from a very severe acidosis. The acidosis was probably a relative one, caused by the loss of alkali from the intestines. It seemed therefore bad practice to give cathartics which would irritate an intestine already too irritated and cause a loss of material from the bowel which it was vitally necessary for the infant to retain. Unless an infant was distended, cathartics were contraindicated; opium was to be given in amount only sufficient to diminish the excessive diarrhea. It was also necessary to give soda by mouth, by rectum intravenously or subcutaneously. The intravenous was the method of choice, if a vein was accessible. It should be given in large doses to cause a cessation of the dyspnea and alkaline urine. This method of treatment improved the likelihood of recovery but did not mean that recovery would inevitably ensue. The severe acidosis might be combated and yet death might take place. In closing, Dr. Howland said that this condition should not be termed "food intoxication"; it was not due to the presence of abnormal substances, but to the absence of substances that were very normal and necessary to life.

Dr. GERSTENBERGER asked Dr. Howland what dosage of alkali he gave by the mouth and intravenously.

Dr. KOPLIK said that opium was a dangerous drug. It was difficult to gauge the dosage in severe cases of diarrhea in infants and he did not see why one should stop diarrhea and peristalsis which was nature's way of eliminating noxious substances. Years of clinical experience had taught him that it was best to treat babies without opium of any kind.

Dr. CHARLES GILMORE KERLEY of New York said opium was one of the best drugs they had if used in the right way. It was indicated in moderate doses sufficient to control the diarrhea.

Dr. ISAAC ABT of Chicago said he would like to hear Dr. Howland's opinion with reference to feeding these babies. The feeding was more important than the giving of alkalies. What dietary measures did he take to prevent acidosis?

Dr. BLACKADER of Montreal, Can., said he was in favor of giving small doses of opium in these cases. Opium sufficient to control the extreme peristalsis in these cases did a great deal of good. Dr. Koplik's statement should not be allowed to go out from this meeting without some modification.

Dr. MORSE said that the question as to whether opium was indicated or not depended on the individual case. If there was something in the bowel which should come out a cathartic was indicated; if the diarrhea was simply draining the tissues, then opium should be given. Another point brought out by this paper was that it was advisable to give alkalies before the appearance of severe symptoms.

Dr. TALBOT said he had recently been studying physiological acidosis, since it was necessary to know about acidosis in normal conditions in order to be able to make comparisons in pathological conditions. In studying 100 new born babies he had found the respiratory quotient very low on the second and third days of life. Such a low respiratory quotient had been found in diabetes and yet no acetone bodies were found in the urine. This substantiated Dr. Howland's statement that a low carbon dioxide tension was found in the alveolar air before acetone bodies were found in the urine.

Dr. HOWLAND, in closing, said a small amount of acetone bodies did not mean acidosis; it was only when the protective mechanism was brought into play that pathological acidosis was produced. When there were no fermentative or putrefactive substances in the bowel and the diarrhea was simply a protective process carried to the extreme, and accompanied by the excretion of a large amount of alkali, then opium should be given, but in small quantities, a few drops after each loose stool. He gave four grams of alkali at a time subcutaneously, five or six grams intravenously and three or four grams by the mouth at a time. The diet was extremely difficult to manage. The majority of these children died but with intelligent treatment it was possible to save more than if the indications for treatment were disregarded.

The Etiological Relationship of Syphilis to Chorea of Sydenham.—Dr. HENRY KOPLIK of New York read this paper. He stated that clinically there was an undoubted relationship between chorea and endocarditis and between chorea and rheumatic joint manifestations. Of late there had been an effort to connect chorea in an etiological way with syphilis. Arsenic had for decades been a favorite remedy for chorea, so that it was natural on the appearance of salvarsan that this remedy should have been tried. Bokai thought salvarsan was of great benefit in the treatment of chorea, especially in cutting short the duration of the affection. From this to the surmise that there was a connection between chorea and syphilis was but a step. The essayist reviewed the reports of various investigators who seems to have observed an association between these two conditions and stated that he had endeavored to enlighten himself as to this relationship. He had made observations on ten successive cases of chorea in his hospital service at the Post-Graduate Hospital. In five of these cases there was an endocarditis at the time of admission to the hospital with an evident lesion of the valves; in three there was a distinct history of rheumatism; in ten a Wassermann test was made, and in eight the result was satisfactorily negative. In two the reaction failed but was not positive. In all cases there was absolutely no stigmata of syphilis, hereditary or otherwise. The presence of syphilis might, of course, be an accidental find as there was no reason why a child affected with syphilis might not contract chorea just as readily as another. Nine children having chorea were injected with salvarsan in doses of varying size. In seven of these no striking amelioration of the symptoms such as had been reported was observed. In another case nephritis occurred and the child was ill for some weeks with chorea although recovery finally took place. In the opinion of the writer they had not in salvarsan an agent of any value above those hitherto employed in the treatment of chorea minor, nor were they warranted in tracing any relationship between chorea and hereditary or acquired syphilis.

Dr. HOOBLER said that Dr. Koplik stated that he had been able to obtain no positive findings from the blood culture in cases of chorea. The streptococcus viridans had been isolated four times from the blood of choreic patients at Bellevue Hospital and a number of times by English investigators.

Dr. E. W. SAUNDERS of St. Louis said that they did not have many definite signs in chorea but there was one sign which he had used for years which was very useful. That was that during the first septima of life when a child was asked to open his mouth he also separated his fingers. The choreic child lost this associated movement at once. He made it a practice to keep a child with chorea in bed and out of school until this association of movements returned.

Dr. ISAAC ABT of Chicago said he had used arsenic in the treatment of chorea for some years but noticed that its use was sometimes followed by neuritis. He had now abandoned the use of arsenic in chorea and relied upon the rest treatment and in cases in which rheumatism was present on the salicylates.

Dr. KOPLIK, in closing, said he had mentioned in his paper that others had found organisms in the blood of choreic patients, but that he had not been successful though he had taken cultures of as many as two dozen cases. He was rather annoyed that others could find organisms that he had been thus far unable to find. Arsenic was useful as a tonic in the treatment of chorea, but he felt rather uncertain as to its usefulness in the disease itself.

(*To be continued.*)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Two Hundred and Seventieth Regular Meeting, Held Friday, April 2, 1915.

Dr. WALTER B. JAMES IN THE CHAIR.

Notes on the Schick Reaction.—Dr. WILLIAM H. PARK made this presentation. He showed two students on whom he had tried the Schick test. Schick had made a test two years ago that was a reversal of the usual laboratory methods, that is he endeavored to get a negative reaction. Roemer had suggested the question whether a neutral mixture could be obtained by injection of toxin and antitoxin, together, intradermally. They now used this mixture of toxin and antitoxin, and if they had any free toxin present they got an inflammatory reaction. Schick tried to find out if there was any free antitoxin in the skin that would neutralize any toxin. He tried 1/50 of the fatal dose for a guinea pig. This was sufficient in a person to make a hyperaemia which later turned into a pigmentation. If, therefore, there was no antitoxin they got the direct effect of the slight toxin. It was the reverse of most reactions; if you got no reaction it showed you had antitoxin, as the toxin was neutralized. The positive reaction was the direct effect of the toxin on the skin. It must be done intradermally, not subcutaneously, with 1/10 c.c. fluid, with a tiny needle, and 1/50 fatal dose of toxin, but a little more did no harm. One of these students had shown a true reaction, with distinct hyperaemia and slight pigmentation, leaving later a brown pigmentation. The other man had a pseudo reaction, which came on more readily than the true reaction, and went more rapidly, leaving no pigmentation. In about 3 per cent. of the cases you got a pseudo reaction, and most experimenters learned to know them. Dr. Zingher had done about 1,000 of these tests and guessed absolutely. A very small amount would cause an anaphylactic reaction in a sensitized person and give a marked reaction.

Dr. LONGCOPE asked how soon the reaction came on.

Dr. PARK said the true reaction took about 36 hours; the pseudo, 24 hours.

Dr. MILLER asked if the test must be repeated if you got a pseudo reaction.

Dr. PARK said that if any pigmentation remained you had had a true reaction. It also gave slight constitutional symptoms.

Dr. LONGCOPE asked why one called a pseudo reaction anaphylactic.

Dr. PARK said they got it in sensitized animals as well as in 3 per cent. of human beings.

Dr. LONGCOPE asked if all patients with antitoxin gave a pseudo reaction.

Dr. PARK said that a pseudoreaction had nothing to do with antitoxin whatever.

Dr. EWING said, as he understood it, there were three types—a true reaction, a pseudo reaction, and no reaction.

Dr. PARK said if one had no reaction there was free antitoxin. The pseudoreaction had to be distinguished from the true. The true reaction was sometimes covered by the pseudo. Twenty-five per cent. of young adults had no reaction. The subject had numerous applications. Schick found that of people over 25 years,

85 per cent. had antitoxin; that is, in adults, only 15 per cent. could contract diphtheria. When, like the student shown, you had no antitoxin, you still might be immune. They were now trying to immunize all the children with the diphtheria bacilli, and not the toxin mixture, and so far they had had no case of diphtheria in the scarlet fever wards, although there were some carriers in the wards. They had found that all those who had antitoxin made antitoxin. The unfortunate group that had no antitoxin made no antitoxin. Diphtheria patients had antitoxin for two months. The diphtheria patients had a positive Schick when they came in. This test could be used to separate all that had antitoxin. Those with a negative Schick would be immune. Once immune you apparently stayed immune. Eighteen years ago Dr. Park said he had swallowed diphtheria bacilli and did not get diphtheria. Dr. Williams had a positive Schick then and now. With a positive Schick you might be susceptible and you might not be. After diphtheria all were immune for a few months, one-fourth to toxin and three-fourths to diphtheria bacilli reaction. A person with a positive diphtheria culture and a negative Schick was a carrier. The bacilli might be non-virulent. You might need to do a second test for antitoxin at the end of 14 days.

Dr. MEARA asked if you could render diphtheria patients immune by the use of the bacillus, as in active immunization.

Dr. PARK said the person had been immunized to the bacillus.

Dr. MEARA said he had understood Dr. Park to say there was usually no immunity.

Dr. PARK explained that there were two kinds of immunity—bactericidal and antitoxic.

Dr. MEARA asked if the recurrence of diphtheria were not unusual.

Dr. PARK said he believed that cases that were called recurrence were really croupous tonsillitis.

Dr. MILLER asked what was a unit for a dose, and if you got necrosis with a very strong reaction, and did the pseudo reaction vary with the character of the toxin.

Dr. PARK said the dose was 1/50 of a fatal dose; if no reaction occurred you doubled it and gave 1/25; if no reaction was obtained then you could give twenty times that amount; you could be sure of no reaction. With a strong toxin a true reaction could be very severe. The pseudo reaction varied with the toxin.

Dr. LONGCOPE asked if skin reactions were obtained with the bodies of the bacilli, and if most people gave a reaction to the bodies themselves.

Dr. PARK said in complement fixation they found very little reaction in the patients, although they were immune. The reaction to the toxin solution was more powerful than with bodies of the bacilli.

Dr. STARR asked if this test applied to anything except diphtheria.

Dr. PARK said no; he thought all other reactions were from the standpoint of sensitization. This was a reaction of the cells direct.

Dr. LONGCOPE asked if a similar reaction had been tried with tetanus toxin.

Dr. PARK said no, that that was a nerve reaction.

Autoplastic Tissue Grafting from Calf of Leg.—Dr. ABBE presented this patient, a girl, 10 years old, who had been knocked down by an automobile and run over two and one-half years before. The right heel had been torn off. The child had been walking for two years on the toes, with the help of a stick. She had a marked talipes equinus. The heel was covered by a thin scar with a hard, tender center crust. Dr. Abbe made a new heel by taking a flap from the calf of the opposite leg, putting the child's leg in plaster of Paris. The thick tissue from the calf made a beautiful cushion heel which would last a life time. The child could now walk, run, and play with other children. The graft had been taken off at the end of 14 days.

Dr. GIBSON said the result was very good. He had done the same thing with an autoplastic flap from the same leg by turning down a flap. The position of the patient was a little less irksome and the flap was fully as efficacious.

The Belgian Red Cross Hospitals of Dr. Depage.—Dr. GIBSON presented this paper (see Vol. 87, No. 17, p. 692).

In reply to a number of questions Dr. GIBSON said he had been most struck with the pluck and spirit of the Belgians in planning for the future. The work of organizing hospitals close to the firing line was being splendidly conducted. The hope was that as the Allied troops advanced former hospitals would be used as a base and new equipments would keep near the trenches. The great need was that the wounded should receive immediate attention. First care made all the difference in the world. The matter of getting to the front was surrounded with difficulties. He had seen no pneumonia. There was much typhoid in the British Army, owing to the fact that typhoid inoculation was voluntary, and the injections were so severe that many refused them. Tetanus, he thought, was a good deal localized. There was nothing done about intraspinal injection; they did not seem to have heard of it, and there was a lack of antitoxin in Belgium. He had heard a rumor that German surgeons were amputating more freely than the Allies. The latter seemed to be saving perfectly useless limbs in many cases. The whole town of Boulogne was practically an English hospital. They were using motor ambulances, mostly Ford. In Belgium these were useless as they broke down on the heavy roads. Mrs. Whitney had turned an old monastery into a hospital for 100 cases. In the American Hospital in Paris 400 cases were being treated. The French plan, however, had been not to bring the wounded to Paris at all. The reason for this was that the Germans had been within 15 miles of Paris. A very pressing need for base hospitals existed. Prompt removal of the wounded was possible in the rear trenches. In the front trenches they had to wait till nightfall, when they were taken in ambulances direct to hospital. The Germans fired upon the rescuers. Dr. Depage had told him that if the wounded did not die at once the mortality was under 10 per cent. There were often rifle wounds in the head. As to insanity, the men were often completely dazed, but after rest they recovered. He did not believe that one shell in 20 did any damage. Of the troops he thought the finest men were from England. The alcohol question had not come up when he was there, but he believed that there was more drinking in England than in other countries. In France the better classes did not drink. It was not considered good form.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held April 19, 1915.

THE PRESIDENT, DR. THOMAS S. SOUTHWORTH, IN THE CHAIR.

Secretin and Its Therapeutic Possibilities.—Dr. J. WALLACE BEVERIDGE, after having referred to the wonderful advance in medicine which had been made during the past decade along the line of a better understanding of the physiological action of the ductless glands and their internal secretions, said that the hormone known as secretin, which was found in the epithelial cells of the mucosa of the duodenum, was unquestionably the most active stimulant to the pancreatic gland known to the physiologist and the internist. Following the earlier observations of Dolinski and Gottlieb and of Popilski, Wertheimer and Le Page, Baylis and Starling, in 1902, had demonstrated the fact that there was something more complex, as an activating agent to the pancreas, than the mere acid reflex previously observed. Pawlow then advanced the theory that such activating agent was not an acid which reflexly inhibited the secretion of the pancreas, but some unknown substance which increased the flow of pancreatic juice either through the circulation or by reflexly stimulating the nervous centers. Later, Baylis and Starling were able to demonstrate that Pawlow was right, and they were the first to prove by experimentation the presence of an excitant —a hormone—which was now designated as secretin. The theory that hormones play a vital part in the chemistry of digestion was thus firmly established; but although more than twelve years had elapsed since the discovery of secretin, little or no attempt had been made to utilize this most available and potent substance for the relief of pancreatic insufficiency and intestinal stasis—a fact perhaps largely due to the circumstance that no one had been able to produce artificially a secretion of sufficient activity to remain stable long enough to discover what results might be observed from its oral administration. The method first indicated by Baylis and Starling was intravenous injection, but this was not practicable because of its instability as prepared by them, which rendered such administration dangerous. Some English observers had asserted that no real physiological action resulted from the oral ad-

ministration of secretin, but from his personal observation he (Dr. Beveridge) was able to state positively that in certain conditions it could be given by the mouth without disappointment and with more advantage than from any other therapeutic agent. Chemically, it had not as yet been shown just what secretin really was. It was not a ferment, but a protein substance of low molecular weight whose activity was greatly impaired by boiling. Its stimulating action on the pancreas was not reflex, but a direct one carried through the blood-stream and probably affecting the secretory cell itself. Delezenne and Frouin had demonstrated that secretin also has an action which increases the supply of succus entericus, and Hallion had shown that, in addition, it increases peristalsis in the small and large intestine. Taking up the therapeutic possibilities of secretin, the speaker said that while he was doing considerable work in diabetes some years ago the interesting fact was noted that gastric hyperacidity occurred in over 80 per cent. of the 300 cases observed. It was reasonable to assume that if there were an excess stimulation, through an acid medium, of the delicate mechanism comprising the epithelial cell of the duodenum for a long period, a deterioration or a distinct destruction of the cell activity would result, and the ability of the cell to produce secretin would be greatly impaired, and, secondarily, the pancreas would to a great extent be unable to supply the secretion required for terminal digestion; and, as result of this condition, the protein molecule would be only partially broken down and the carbohydrate molecule remain in an incomplete state of separation. Theoretically, the exhibition of secretin should aid in overcoming the breaking down of these molecules; but clinically this was not found to be the fact, and in these cases—in which he gave secretin in periods ranging from three to seven months—in no instance had he observed any change in the sugar output. There was, however, a distinct action upon protein, though whether or not this was due to increased activity of the pancreatic secretion would require further investigation. It was a fact that after secretin had been taken for two or three weeks a material increase in the urea output was noted. In a series of over 100 cases of thyroidism accompanied by chronic constipation of from five months' to eight months' standing, intestinal stasis had been one of the predominating features observed. In conditions with chronic stasis the gastric acidity, at first increased, eventually became greatly diminished, and this would result in a marked decrease in the production of secretin in the duodenum, with accompanying reduction in the pancreatic secretion. When this occurred the protein molecules were never completely broken down, and one of the main etiological factors in all thyroid conditions was the absorption of excess of protein, or protein which had not been broken down to the amino acid stage required in normal digestion. In the medical treatment of stasis the mineral oils, while of great assistance, acted only in a mechanical way, having no physiological action whatever. In cases of impaired metabolism something more was needed than a mere mechanical agent, and secretin furnished a satisfactory solution of the problem. In it we had a substance which acted in two distinct ways: increasing peristalsis, and aiding in the normal digestion of protein. This series of cases were nearly all radiographed by Dr. A. J. Quimby, and he had reported that after the systematic administration of secretin stasis no longer existed. Furthermore, under this remedy the symptoms of malaise and the pains in the knees and calves of the leg, with severe headache, entirely disappeared. The urea output, which had been uniformly subnormal, became normal, and tachycardia, present in over 60 per cent. of the patients, was diminished. For the postoperative symptoms, such as severe constipation and continued vomiting, after such procedures as gastroenterostomy and jejunostomy secretin had proved of distinct value, and in nephritis of intestinal origin it was one of our most efficient therapeutic agents. Although in the way of clearing up indicanuria he did not believe it had such a direct beneficial influence as the culture of the *Bacillus bulgaricus*, through its action in stimulating peristalsis and assisting the complete digestion of protein it aided materially in ultimately overcoming intestinal putrefaction more thoroughly and permanently than could be effected by any other means. Eventually, also, the albumin disappeared from the urine. If secretin were prepared as it should be, there could be no question that distinct results would follow its administration by the mouth; but in standardizing this substance it was necessary that considerable care should be used in its preparation. For its artificial production the duodenum of the pig was preferable to that of other animals because of the varied character of the food eaten by the pig. The process employed by Dr. Beveridge was different from that advocated by Starling. After the duodenal mucosa had been scraped and cleaned it was macerated, and a small quantity of hydrochloric acid added. It was then heated in a beaker or other suitable vessel for from three to five hours and completely digested, the temperature never being permitted to rise above 210° F. During the process of heating from 1 to 2 per cent. of the salts of the blood serum were added, and finally, after filtering, sufficient glycerin and alcohol to preserve the preparation. Ordinarily secretin was an unstable, readily oxidizable product, and unless it was fixed in some way its activity was quickly lost. Furthermore, he had found that if secretin alone was injected into the blood-stream, no pancreatic secretory excitation occurred, and the same negative result followed the similar injection of an acid, of blood serum salts, or of Locke's physiological solution; but if secretin were thus injected in combination with serum salts or the Locke solution, there was noted an immediate response in the secretory activity of the pancreas. The same result was observed in the oral administration of secretin, and the addition to it of blood serum salts was therefore essential. By way of summary it might be said: (1) Secretin is indicated in all pancreatic insufficiencies in which true organic changes have not occurred. (2) It may be employed to advantage in secondarily aiding protein digestion. (3) It constitutes the most important factor in causing a low urea output to rise to normal. (4) It has no power to aid in the digestion or breaking down of the carbohydrate molecule. (5) It is indicated in gastroenterostomy and jejunostomy. (6) It is of distinct value in nephritis of intestinal origin. (7) It increases peristalsis and is indicated in all cases of intestinal stasis.

Dr. William Van Valzah Hayes said that up to the present there had been some uncertainty regarding the action of secretin because it had not been sufficiently standardized. Personally, his practical experience with it had not been large on this account, and he was very glad to have the definite information on the subject given by Dr. Beveridge. If we had an entirely reliable preparation which could be administered by the mouth it would undoubtedly be a very valuable addition to our therapeutic resources. In some cases he had observed secretin had appeared to do wonders. As to its action in the stomach he would like to ask Dr. Beveridge how it affected the gastric secretion—did it increase the hyperacidity? If by means of it we could increase a low urea output it would certainly be a great gain. The medical profession, he thought, had not yet availed itself of the great possibilities of this agent because there had been no standardized, dependable preparation for general use, and it was to be hoped that the expense of such a preparation would not be prohibitive.

Dr. Rolfe Kingsley said that nearly all those using secretin had, because of its having a characteristic action, employed it in the treatment of diabetes, but it had been found to have no effect on the sugar in the urine. It was observed, however, that diabetics taking it gained in weight and were greatly improved in general health. This was now explained by Dr. Beveridge, who had shown the favorable action of secretin on protein metabolim and its effect in relieving intestinal stasis. Some years ago this agent was employed in about thirty cases of diabetes at the Vanderbilt Clinic, under the supposition that in its action on the pancreas was included an effect on the islands of Langerhans, but the results observed were entirely disappointing. Dr. Beveridge had stated that in the preparation of secretin it was essential that the boiling point should be avoided, but it was a fact that the secretin used at the clinic had been boiled for four hours.

Dr. Henry R. Harrower, having urged the need for a more extended consideration by the profession of the therapeutic possibilities of secretin, said he recalled some experiences in the treatment of conditions associated with low total solids in which the urea output was materially increased after a course of buttermilk given several times a day, and it seemed to him very likely that the lactic acid acted in the same way as the normal gastric acid, by releasing prosecretin from the duodenal mucosa and thus stimulating the whole digestive process. An important field for the use of

secretin preparations was in the digestive disturbances of children, especially summer diarrheas and marasmus, and he had published a paper regarding this in *Pediatrics* in 1913. Here the good effect was no doubt largely due to the re-establishment of the normal production of the digestive juices, the most efficient of all gastrointestinal antiseptics. Another field for the use of secretin which had not been mentioned was cancer, on account of the value of this agent as a means of promoting nutrition. In sarcoma, achlorhydria was the rule, and secretin liberation was reduced to a minimum because of the lack of the hydrochloric acid stimulus to the duodenum; hence, the exhibition of secretin, although it had no influence on the disease itself, would act as a natural stimulus to the digestive cycle, and should therefore prove of material service.

Dr. WILLIAM E. FITCH said that notwithstanding the contention of some of the English authorities that secretin has no physiological action when administered by the mouth, his personal experience had thoroughly convinced him that it is a potent agent when given in this way. In his own case its oral use had completely relieved him of intestinal stasis. When he stopped its employment for a time he found that the symptoms returned, as evidenced especially by putrid gases and putrid stools; but, after he had taken for a few days a dram of secretin solution three times a day these entirely disappeared. From his personal experience, therefore, as well as from his observation of its effects on others, he was an enthusiast for secretin.

Dr. A. JUDSON QUIMBY said that after having seen so many of the worst types of stasis, such as often come to the *x*-ray specialist for examination, the impressions received from the examination, following the taking of a bismuth meal, of the intestinal tract of patients who had been treated by secretin had been very gratifying. Practically no ileal stasis existed, and the delay in the colon was materially reduced. If, in the *x*-ray examination, the ileal contents were seen to remain very flocculent or fluid, and pass through the lower ileal coils in a thin stream, so that the colon received the entire amount within the normal period after the meal had left the stomach, it could be asserted that ileal stasis was absent. Again, after the administration of paraffin oils and similar laxatives this flocculent appearance of the contents of the upper ileum was frequently noted. These characteristics were observed by him in the cases treated by secretin and submitted for *x*-ray examination. Having followed with interest the progress of the several patients so examined from time to time during their treatment with secretin, he could say that he had been suprised and delighted at the remarkable improvement shown in their condition.

Dr. BEVERIDGE, in answer to Dr. Hayes' question, stated that in his cases gastric hyperacidity often seemed to have been improved.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

FUNCTIONS OF THE CEREBRUM. By SHEPHERD IVORY FRANZ. Vol. XIX, No. 1 of The Psychological Monographs. Published by Psychological Review Company. 161 pages.

QUIZ-COMPENDS, Chemistry. By DR. HENRY LEFFMAN. Published by P. Blakiston's Son & Co., Philadelphia. Sixth Edition,—Revised. 241 pages. Price $1.00 net.

AN ADULT WITH STATUS THYMICO-LYMPHATICUS OF THE HETEROSEXUAL CHROMAFFIN TYPE.

BY HARRIS A. HOUGHTON, M.D.,

BAYSIDE, LONG ISLAND.

VISITING PHYSICIAN TO THE FLUSHING HOSPITAL.

CASE reports of patients who show evidences of status thymico-lymphaticus are not many except as the condition has been uncovered at autopsy. In those few instances, where the diagnosis has been successfully made during life, the heterosexual characteristics have been depended upon to reveal this state and no especial effort has been made to detail other clinical associations. At autopsy, the incidence of status thymicus is known to be large, probably as many as three out of each hundred persons having what may be termed a pathological thymus gland. It assumes great importance in infections associated with nutritional disturbances, as such individuals are known to have low resisting powers. Hitherto, attention has been largely directed to sudden death in children, especially during anesthesia. The possibility of sudden death in adult life has not received much notice. Its importance as a factor in the etiology of exophthalmic goiter has been realized only lately (Halsted[1]), and especially in the treatment of that disorder by *x*-ray (Waters[2]). There has been no general attempt to study abnormal sexual events such as delayed puberty and climacteric from this standpoint and especially the neurotic disorders of the climacteric period. Thymic gland feeding has been shown in one case to have developed sexual life in a boy (Kerley and Beebe[3]). So little is really known of thymic glandular physiology, or of the influences which tend to its persistence or which tend to inhibit its normal involution that it will be best to define the terms to be used and temporarily justify the classification suggested by the title.

Unfortunately an attempt of this character is not possible without the appearance of drawing conclusions however innocent intent may be. In any event, further experience will modify conceptions. The term "status thymicus" will be used to indicate the presence of an enlarged thymus gland irrespective of its activity and irrespective of whether it should be classed as a permanent persistence of a gland enlarged at birth, whether it should be classed as a gland which has simply failed to properly involve, or whether reenlargement has occurred following normal involution. No standard of normality has ever been satisfactorily demonstrated, Hammar's work[4] probably approaching closer to accuracy than any other. His conclusions are based on the findings at autopsies of normal people of good nutrition who had died by accident. Nor is there any clinical measure of its normal or pathological activity at different periods of life. In conditions of hyperactivity other endocrine glands are sooner or later involved, such as the chromaffin system, the hypophysis, the thyroid, the lymphatic structures generally, and possibly the pancreas. This case, with others to be reported later, is assumed to be an instance of hyperthymization (at least during middle life), the diagnosis resting on primary and secondary symptomatology and the obviously hyperplastic condition of the gland as shown by fluoroscope and skiagram.

The old term "status lymphaticus" should be discarded until it can be shown that a genuine lymphatic struma exists without status thymicus. The complex which was formerly so-called, and which is held responsible for sudden infantile death and ether collapse is in reality as suggested by Wiesel,[5] status thymico-lymphaticus. This term presupposes a hyperplastic thymus associated with hypoplasia or hyperplasia of the mesenteric and retroperitoneal glands and general change in the enteric lymphoid tissue. The superficial lymph nodes of the body, including the tonsils, and the nasopharyngeal lymphoid tissue are sometimes involved and there is often found a lingual tonsil.

To this syndrome should be added the secondary heterosexual characteristics described by Haven Emerson,[6] viz., scantiness of hair and its distribution which with the general corporal contour, all tend to approximate that of the opposite sex. These characteristics place the diagnosis of status thymico-lymphaticus, though indirect, on a firm basis. No feasible method of establishing a diagnosis in status thymicus without these sexual evidences has yet been advanced. There are some reasons for believing that cases showing the sexual characteristics should be classified as preadolescent types, and that others not showing these characteristics should be classed as post-adolescent types, or perhaps cases of true thymus hyperplasticus.

As pointed out, status thymicus is known to be associated sooner or later with other ductless gland disturbances, apparently on the principle enunciated by Marie that oft-repeated hypersecretion of a ductless gland eventually leads to exhaustion, or that a condition of exhaustion may immediately obtain if the irritation is sufficiently intense to overpower. Low blood pressure and chromaffin exhaustion have long been associated with the thymic state, and the association confirmed at autopsy. From a pathological standpoint the association with chromaffin hyperplasia has also been noted. If, therefore, "status thymico-lymphaticus of the heterosexual chromaffin type" is used to describe the primary conditions found, the involvement of other endocrine glands than the thymus is presumed from the clinical ensemble.

Agnes C. was one of the first cases studied. The problem was to demonstrate the presence of the gland by some direct method of examination. The *x*-ray plate (Fig. 3) did this, but no other method would have served the purpose. In outlining the

Fig. 1.—Agnes C., (Flushing Hospital, Ward No. 353, Medical). Status thymico-lymphaticus of the heterosexual chromaffin type. Note the masculine contour of the face, neck, chest, and especially of the arm, with the biceps taut. The breasts during middle life were never large and are now atrophied. The hands are coarse and of a masculine type. The front hair is false, her own being short and scanty. (Photo by Russell.)

heart, percussion led to false conclusions, as the presence of tuberculous lesions near the right auricle and left ventricle changed the character of the note at a point external to actual cardiac dullness. This being true with reference to such a constant organ as the heart, and the impossibility of definitely excluding tuberculosis in the region of the thymus except by *x*-ray defeated attempts at the diagnosis of enlarged thymus by percussion. After viewing the plate, it was thought that auscultatory percussion and auscultation of the voice yielded some changes, but the results were not sufficiently definite. The organ could be roughly outlined under very favorable conditions by the fluoroscope, but the tuberculous lesions again prevented the characteristic movements (*vide* Houghton[7]).

The medical history of Agnes C. is tedious. Patients of this class are usually sickly and their complaints varied. Often these complaints are assumed to be without significance, but viewed from the standpoint of endocrine disturbance, these subjective symptoms appear in a new light.

Agnes R. C., aged 56 years, a widow of ten years, and one child now 26 years of age. She is a "practical nurse." Referred by Dr. F. L. Satterlee, Sr.

Complaints.—Dyspnea on exertion. Headache, parietal, daily. Feels as if her heart were "too big for her body," a symptom from which she has suffered for many years. The heart occasionally stops and starts with a bound. She has occasional acute pains in her ovaries.

Family History.—Her father died suddenly from heart failure; had been sick in bed some time prior to death. The heart is said to have failed during an attack of acute indigestion at the age of 76. Her mother died at the age of 76 from cancer of the uterus. She had been a nervous invalid for many years before climacteric, but the later years of her life were comfortable. Nothing further is known of previous generations. A brother in middle life has had paralysis; a brother died in infancy from "dropsy following measles;" a sister died of smallpox; a brother died of pneumonia at 52 years; a brother died at 40 of "heart trouble;" a sister died of cancer of the breast; a sister died in adult life of "clot on the brain;" a sister died at 3 months suddenly of "congestion of the lungs."

Early Life.—She was breast-fed. At nine days of age an attack of "whooping-cough" began from which she did not recover for many months. Measles at 5 years of age. Suffered much from ear-ache. Otherwise her childhood appeared to be a normal one. She was fond of play and her parents apparently indulged her a good deal.

Menstrual and Sexual History.—She began to menstruate at 15 years of age. She was married at 26 years. Between these two dates her menstrual periods were painful, the pain coming on coincident with the flow, and the amount of flow was scanty. She could always tell when periods were impending by the frontal headache which preceded them and lasted 24 hours. These were accompanied by attacks of intense nervousness, which usually lasted through the flow. Three to four day flow. After marriage these symptoms lessened. At 27 years of age had a five months miscarriage from unknown causes. This was followed by a phlebitis of the left arm and leg, the marks of which in the form of enlarged veins are still apparent. At 30 years she had a living female child. During the early months of pregnancy she suffered much from vomiting, and in the later months from headache. The fifth month of gestation was accompanied by an attack of paralysis which involved the left side, arm and leg, and which persisted until the child was born. I have been unable to learn the exact nature of this illness. She has no signs of this now. At 52 years of age her

Fig. 2.—The colon forty-eight hours after ingestion of the bismuth meal, and showing complete ptosis and elongation of the transverse colon and the presence of fecoliths in the cecum. The position of the hepatic flexure is normal, but the fixed position of the median portion of the transverse colon in contact with the cecum in successive pictures suggests the presence of adhesions. The usual preparation for *x*-ray examination was supposed to leave the gastrointestinal tract comparatively clean, but the presence of these hardened masses, some of which were subsequently recovered, raise the question as to how long they have been there, by what they had been caused, and what other effect than the presence of large amounts of indican in the urine, have they had on the organism. (Radiograph by Dr. F. L. Satterlee, Jr.)

climacteric began and lasted for three years. It was accompanied by intense nervous reactions, "hot flashes," palpitation, and headache.

History during Middle Life.—After the miscarriage she noticed that "her heart was going bad." This consisted chiefly of attacks of palpitation which sometimes

lasted for half a day and which weakened her a great deal. Her physician said that she had no organic difficulty, but that it was a "nervous heart." Another told her that the attacks came from "indigestion." She was told not to do any large amount of work and to rest frequently.

For ten winters, beginning at 32 years of age, she had periods lasting from two weeks to two months of what she termed "grip." They were characterized by coughing of the tracheal type, no expectoration of account and no fever. Following the birth of her child at 32 years of age she had a "torn womb" with backache. The tear was repaired, and the cervical stitches were accidentally left in. This operation was followed by three attacks (severe) of "nervous prostration" during the following nine months. Inquiry elicited the fact that during this period her chief complaint was early tire on exertion and muscular weakness.*

As she complained of metrorrhagia, a physician examined her and found the stitches. She was then again operated upon, a femoral hernia was repaired and the stitches which had apparently caused the nervous condition, were removed. The uterus was also curetted, and some surgical work was done on the rectum of which she does not know the nature. Her appendix was also removed. She was very sick for days after the operation and was finally told by the surgeon that she had collapsed on the operating table and that all the work which he had intended to do had not been done.

The nervousness continued, and at 46 she began to complain of digestive symptoms. These finally crystallized themselves into the following: Attacks sudden,

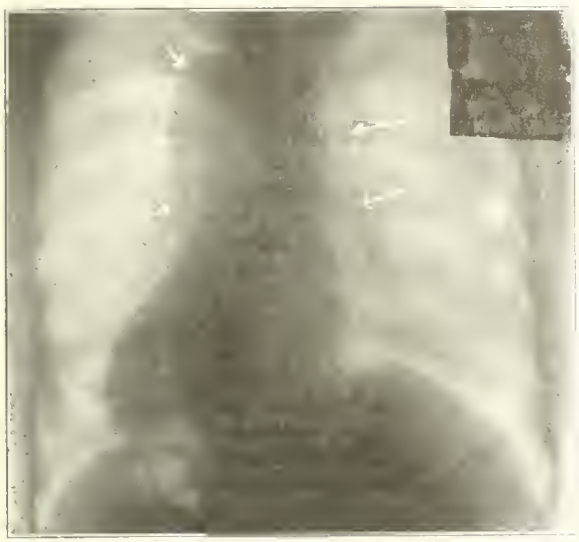

Fig. 3.—Showing the typical appearance of the chest x-ray picture in status thymicolymphaticus. The shadow of the thymic gland is marked by the arrows. The aortic arch and cardia are ptosed and the aorta presumably elongated. Premature calcification of the ribs is very evident in the original plate. (Radiograph by Dr. F. L. Satterlee, Jr.)

coming on at any time without cause, and consisting of pain in the abdomen. She would lie flat on her face, unable to move until they eased. This was finally diagnosed as gallstones and she was operated upon. This was at 53 years of age. She was eleven weeks in bed with a phlebitis of both legs. For a time she was much better of her symptoms (excepting the nervousness), but a year ago they began to return and she was advised to be operated upon again for the gall-bladder trouble. She went to the hospital for that purpose, and when her medical history was taken, and compared with her previous record at a former hospital, she was told that to operate her would mean "sure death" and that they would under no circumstances give her ether. The

*It is evident from my cases that this is a most characteristic symptom of status thymicus. The typical history as given by a patient recently is "I awake in the morning feeling splendidly though the night's sleep may have been poor. My first thought is as to how much I can accomplish during the day. After a good breakfast, I take a walk as I have been advised to do, and before I have gone two blocks I begin to feel tired. If I continue, I am compelled to sit down and rest before a half mile is covered, and for the rest of the day my strength is gone."

digestive symptoms have persisted but are growing milder.

Four months ago she went to Dr. Satterlee, whom she had not seen for several years, complaining of her heart and dyspnea. He found that her systolic arterial pressure was 262 mm. Between that time and the time when I first saw her, she was treated with aconite in small doses. Once, Dr. Satterlee informs me, the pressure touched 230 mm. of mercury. During the week previous to my first examination, medication had been discontinued.

The General Examination.—The picture illustrates the general masculine contour better than any description. The legs and feet were in harmony with the evident structural trend. The bones themselves were inclined to be small. The pupillary and various tendon reactions were inclined to be hyperactive. The skin presented a muddy appearance, though this was not marked. A possible hypothyroidism was indicated by freedom from moisture (she states that she never sweats) and by a slightly enlarged but firmly knit thyroid gland. The hair had the typical distribution. That of the head was sparse, short, and coarse. Occasional hair on the face. The axillary and pubic hair was scant, and the latter showed the masculine distribution. The skin of the abdomen was loose, with little subcutaneous fat, and scaly in areas. It apparently had no life. She stated that all her life, "black and blue spots" from bruises persisted longer than they do in normal people, and appeared with less contusion. The nails were broad and thick, and presented longitudinal rugæ. There was marked dermagraphia (which disappeared after treatment) and erythema, multiformis which rapidly appeared and disappeared especially on the chest. The breast tissue had atrophied. The nipples were small.

The physical examination of the chest revealed various areas of moderate emphysema, and prolonged expiratory murmur with moderate rise in pitch. The percussion boundaries of the heart would have led to a diagnosis of cardiac dilatation had not the examination been checked by the x-ray plate. The thymic shadow is sufficiently characteristic so that a diagnosis would have been possible without further evidence. The action of the heart was strong, perhaps too much so even with the high arterial tension. There was a marked shortening of the systolic pause, and a slight soft systolic murmur heard best in the sixth interspace on the right side. The spleen and the liver were both normal in size. There was a deep boggy feel in the iliac regions, and fecoliths could be distinctly palpated. There was sufficient weakness with ptosis of the anterior abdominal wall to justify a diagnosis of general enteroptosis. Right kidney movable. The uterus was slightly enlarged and partially fixed in moderate retroversion. Apparently there was a small fibroid near the left cornu. The left ovary was slightly enlarged and prolapsed. Perineum normal.

The nose and throat examination by Dr. Bardes disclosed no lymphatic hypertrophy in the turbinates. Lingual tonsil and adenoids absent. The tonsils were present but normal involution had occurred.

Laboratory Examinations. (By Dr. A. F. A. Wiggers.) The Urine: 24-hour specimen; 1000 c.c. passed. Sp. grav. 1.018; clear, amphoteric. Negative as to albumin by heat, Robert's test and Esbach's test. Negative as to sugar. Diazo, acetone, and bile, negative. On a basis of + as normal, the indican was ++++. There were a few hyaline, and coarse granular casts, a few oxalate crystals in the sediment.

Gastric Contents:* Test meal withdrawn one hour after administration: Free acidity, 24; combined, 56; total, 80. Microscopic examination negative.

The Blood: Total erythrocytes, 5,000,000; hemoglobin, 95%; index, .95; otherwise negative; total whites, 5,800; polymorphonuclears, 67%; small lymphocytes, 30%; large lymphocytes, 2%; eosionphiles, 1%.

A raw beef sandwich was given late in the evening and the stool of the following afternoon examined; it was a formed, brown stool of normal odor. There was nothing suggestive macroscopically. Microscopically, the food had been well digested. The muscle fibers were either faint or had disappeared and there was no indication of parasites. The differential bacterial count revealed a decided tendency toward suppression of the

*I was unable to obtain a satisfactory specimen of duodenal fluid. This often occurs in patients who on x-ray examination show a marked gastroptosis with gastric myasthenia.

coliform type and predominance of the Gram-positive cocci.*

		Normal

Other negative rods	12.0	25.3
Negative cocci	21.8	8.4
Gram positive organisms:		
Positive rods	9.4	5.7
Positive cocci	51.3	11.3
Oval free spores	0.0	1.4
Spherical spores	0.0	.9

The approximate relation of living to dead bacteria as shown by capacity to take stain, 1 to 2.

The Report of the Radiographer, Dr. F. L. Satterlee, Jr., is as follows: The stomach presents a seven inch ptosis, with appropriate ptosis of the transverse colon as shown. The stomach is large and myasthenic, the peristalsis slow (by fluoroscope), and the peristaltic indentations shallow. The cecum and hepatic flexure were in normal position; the former was dilated. The transverse colon was looped. The general motility of the colon was slow and the presence of fecoliths plainly outlined.

Discussion.—The diagnosis of status thymico-lymphaticus appears to be complete, as shown by the portraits and the *x*-ray plate of the chest. The masculine contour, the sparsity and distribution of the hair, the presence of a few enlarged lymph glands in the groin, the aortic and cardiac ptosis are all parts of a complete clinical picture. It remains therefore to draw attention to certain clinical associations, the presence of which may disclose leads for future observation in other morbid conditions.

The Family History.—The association of chromaffin disturbance as shown by the high blood pressure appears in other members of this family, both in the same and in preceding generations. There have been no known instances of sudden infantile deaths† so far as could be learned, nor is it possible to obtain a history of difficulty in breathing after birth, which is often obtainable. Agnes C. has a daughter now twenty-two years of age who is said to be a "nervous wreck," and who has a "neurotic heart," which often keeps her in bed. She in turn has a daughter now two years of age. There was slow nutritional development in this child during the first year of life. They live at a distance and the opportunity to examine them has not presented itself.

Sexual Life.—This shows a marked deviation from the normal. Puberty and climacteric were both delayed. Neurotic disorders attending early menstrual periods, the flow was painful and scanty and the pregnancies were attended by unusually severe toxic symptoms. The climacteric period lasted three years and was of a type which is familiar to every physician, for so little success attends its treatment. There is some ill-defined antagonism between the glands of generation and the pars posterior of the hypophysis on the one hand and the thymic gland on the other. Under-development of the sexual organs, penis and testicles of under-size, accompany status thymico-lymphaticus and are external manifestations of that condition making possible a diagnosis in certain instances (v. Neusser[9]). In this connection the case of Kerley and Beebe[3] above referred to is interesting. The thymus gland persists in eunuchs. Anomalies of menstruation might profitably be regarded as manifestations of endocrine perversions such as hypothyroidism and thymic subinvolution and treated as such. The results might justify the attempt.

Anesthesia in Status Thymico-lymphaticus.—This patient has undergone two major abdominal operations. The first was apparently uneventful. The second was accompanied by collapse. The third was never attempted, for evidently the true condition was suspected. It does not appear, therefore, that all status thymicus or status thymico-lymphaticus cases pass out when under ether. Nor is it conceivable that this is true even in infants. Lange[10] has suggested that enlarged tonsils are simply manifestations of thymic activity, and that the involution of those lymphoid nodules accompany the normal involution of the thymus. What is the determining factor—the one that results in death? There is some good evidence that sudden enlargement may be concerned in the result.[11] It is to be noted that in Haven Emerson's series,[6] which consisted of 288 cases at autopsy, no other cause could be found in twenty-six cases (9.02 per cent.). Death in adults has rarely been attributed to the thymus gland alone, and only at autopsy. Yet here is evidence that the thymic state is concerned to some extent. In adults thymic death is a cardiac death; in children, respiratory. It may occur independent of shock or etherization. Some unknown factor participates, the nature of which is not yet clear.

The Gastrointestinal Tract.—So far as examination could disclose the digestive and assimilative powers of Agnes C. were normal. There was an excess of indican in the urine which proved on observation to be persistent. Obviously this is traceable to the fecoliths in the flexures of the colon, or the partial stasis. She did not complain of constipation and were it not for the *x*-rays nothing would have been known about constipation. In this case, the indican is a manifestation of colon irritation and fecolithiasis rather than poor protein assimilation in the small intestine. The *x*-ray plate also shows the complete ptosis of the transverse colon and of the splenic flexure. The hepatic has retained its position. This appears to accompany the ptosis of the cardia and aortic arch and harmonizes with the chest findings. It appears to be a reflexion of the lack of general tone, muscular and otherwise. One cannot refrain from calling attention to the fact that the enteric, retroperitoneal and mesenteric lymph nodes are presumably enlarged, as they are in all such cases. v. Neusser[9] in his monograph devotes attention almost exclusively to the sexual associations of status thymico-lymphaticus, but calls especial attention to what he calls the abnormal length of bowel which he noted at autopsy. This is practically "ptosis." Shiota[11] also speaks of the abnormal length of appendix found in his series. Lymphoid tissue is scattered throughout the intestinal tract and is especially highly developed in the appendix. The association of lymphoid exhaustion or hyperplasia in those who suffer from chronic appendicitis has been noted many times before, and here again it is customary to speak of normal involution of the appendix, or "recessional" cases.

Calcium Metabolism.—In Agnes C., calcium metabolism has been abnormal, as shown by premature calcification of the ribs. Radiographers have been in-

*After the method employed by MacNeal, Latzer, and Kerr.[5] The results obtained from a routine examination of the bacteria of the stools by this method have convinced me of its consistency, the counts in presumably normal people showing constant relations. As in the above case, many show variations, but clinical associations have not been sufficiently constant to warrant any conclusions. The relation of "living" to "dead" bacteria in this case is very high, such as is usually found with hypermotility of the gastrointestinal tract, as in gastrogenic diarrhea.

†A possible exception is the death of a sister at 3 months of "congestion of the lungs." The patient was unable to detail this event, except that the child was sick only 24 hours and the chief symptom was dyspnea.

clined to attribute this to pulmonary tuberculosis. Status thymicus is often accompanied by tuberculosis and it would be impossible to state which is the primary cause in this case. There are many who hold that rickets is a disease caused by abnormal conditions of the thymus gland.

The Blood.—The hemoglobin and hemoglobin index were normal. Before treatment the differential leucocyte count was normal and there was absence of the typical thymic picture of lymphocytosis of the mono-type. The institution of treatment by *x*-ray irradiations applied to the thymic area apparently caused the thymic picture to appear.

Total white cells 5,000; polymorphonuclears, 50 per cent.; small lymphocytes, 42 per cent.; large lymphocytes, 6 per cent.; eosinophiles, 2 per cent.

Pappenheimer has noted that after surgical removal of the thymus gland from white rats the relative proportion of lymphocytes in the blood diminished for the first few weeks after operation.

The Vascular System.—The association with high arterial tension as manifesting hyperplasia of the chromaffin system is important from many standpoints. The classical association with status thymico-lymphaticus is that of hypotension or chromaffin exhaustion (Wiesel[12]). *X*-ray treatment directed to the thymic region caused a marked lowering of the hypertension, in this case the pressure going in less than a week and after two treatments from 265 mm. to 195 mm. (administration of 4 H. units). There was a tendency to rebound, but it has failed to return to the old high level. The pressure seems to be exceedingly sensitive to the *x*-ray, ½ H. for purposes of fluoroscopy causing a marked drop. The decline was of course accompanied by the usual muscular weakness which follows reduction by other methods such as bleeding and aconite.

IDIOPATHIC HEMORRHAGIC MULTIPLE SARCOMA OF THE SKIN (KAPOSI).

WITH SPECIAL REFERENCE TO EARLY DIAGNOSIS.

By FRED WISE, M.D.,

NEW YORK.

INSTRUCTOR IN DERMATOLOGY AND SYPHILOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY; CHIEF OF CLINIC, DEPARTMENT OF DERMATOLOGY AND SYPHILOLOGY, MT. SINAI AND BETH ISRAEL HOSPITALS; ATTENDING DERMATOLOGIST, MONTEFIORE HOME AND HOSPITAL.

(From the Department of Dermatology and Syphilology, College of Physicians and Surgeons, Columbia University.)

THE early recognition of some of the rarer and more obscure dermatoses which the specialist now and then encounters, not infrequently constitutes a powerful weapon of defense, therapeutically, much in the same way as it does in syphilis, cancer, and many other maladies. This is especially true of those diseases of the skin, fortunately few in number, in which the prognosis as to life is very unfavorable, as, for example, mycosis fungoides and pemphigus. Unfortunately, the great majority of patients afflicted with grave disorders of the skin first come within the ken of the expert diagnostician (especially in dispensary practice) at a time when the malady has already made serious inroads and the damage is irreparable, or, at the most, when it is in such a stage as to lend itself only to palliative measures. It is quite likely that the high mortality figures of certain insidious dermatoses, such as the two diseases above mentioned, would be greatly lowered were it always possible to recognize the clinical manifestations of such maladies in their very incipience, and thus be enabled to take offensive measures in good time.

Diagnosis based on the recognition or identification of the earliest manifestations of certain cutaneous affections is often beset with difficulties, more especially in those instances where, for one reason or another, excision of tissue for microscopic investigation is impracticable, or where permission for biopsy cannot be obtained. We must also admit, incidentally, that even microscopic studies of early lesions, in cases clinically obscure and unidentifiable, do not invariably supply us with the missing links in the chain of diagnostic polemics. A puzzling clinical picture frequently goes hand in hand with a perplexing, or rather an undecisive, histopathological section.

Generally speaking, the clinical diagnosis of the vast majority of skin diseases rests upon either the peculiarities of an individual characteristic lesion, such as the flat, glistening, papule of lichen planus, the unbilicated body of molluscum contagiosum, the "apple-jelly" nodule of lupus, the cupped crust of favus, etc., or, on the other hand, it is dependent upon the appearance of the whole or the greater part of the eruption, as in pityriasis rosea, mycosis fungoides, xeroderma pigmentosum, the various drug eruptions, the acute exanthemata, etc. Oftentimes we are confronted with eruptions in which both these factors have to be carefully considered, *i.e.* the individual efflorescences themselves, as well as their arrangement, distribution and areas of predilection—before we are able to arrive at the correct interpretation of the lesions. An isolated patch of pityriasis rosea, for example, may very easily be confounded with ringworm, syphilis, seborrhoic eczema, etc., if the rest of the eruption be ignored or overlooked. The same holds true for many diseases of the skin—their diagnosis is based upon the *tout ensemble,* rather than upon any individual lesion.

The case herewith recorded is an interesting and unusual example of a dermatosis which, seen in its earliest stages, presents a clinical picture subject to various interpretations. The fact that a microscopic examination served to remove all doubts as to the true nature of the disease does not in any way detract from the interest which attaches to the case. It is reported partly on account of its rarity, but chiefly to emphasize the points mentioned in the preceding paragraphs.

The patient, Mr. R., aged 51, married, was referred to the writer by Dr. Louis Jacobs, of New York. He is a Hebrew, born in Galicia. His family and personal histories are entirely negative. His parents died of old age. He is the father of eight healthy children. He does not remember ever having had any illness.

Examination.—The patient is a healthy looking, mus-

cular and wiry individual, who appears to be much younger than his given age. General physical examination reveals nothing abnormal. The Wassermann test, urinary and blood examinations are negative. There is no adenitis; the mucosæ appear to be normal.

Fig. 1.—Idiopathic hemorrhagic multiple sarcoma of the skin (Kaposi). Showing the plague on the tip of the nose and the small nodule beneath the left eye.

The eruption first appeared about six months ago, in the shape of bluish spots on the inner surface of the left thigh, unaccompanied by pain, itching, or other sensation. A month later, he noticed a small, purplish patch on the tip of the nose and a small elevated nodule underneath the left eyelid. Since that time, new lesions of similar appearance, occurring on the lower extremities, attracted his attention. One of these, situated on the dorsum of the left foot, was slightly tender on pressure.

Eruption. The distribution and appearance of the lesions were as follows: A hemispherical, split pea sized nodule located just beneath the lower eyelid on the left side. It had the solid consistency of an unresolved acne papule, was dark purplish-blue in color, rather sharply defined, deeply imbedded in the skin, and smooth to the touch. It presented a glistening surface. On pressure with a piece of glass the color faded considerably, suggesting a growth of angioma-like structure.

On the left side of the tip of the nose, occupying an area about the size of a dime, was a light violaceous plaque, circular in outline, rather well defined, the surface being smooth, glistening and level with the surrounding skin. On palpation, no infiltration or other change in the consistence of the patch could be felt. Pressure here elicited slight pain.

Midway between the wrist and elbow joints, on the flexor surface of the right forearm, was a lentil sized, slightly elevated, reddish violet, flat papule, its periphery sharply defined, its surface smooth and glistening. It was slightly infiltrated.

On the inner surface of the left thigh, midway between the groin and knee, were three separate lesions consisting of slightly raised, smooth, purple plum colored, flattened nodules, each about the size of a dime. At their edges, the purple color gradually faded off to a light violet. The palpating finger met with distinct resistance in these lesions.

On the dorsum of the left foot, overlying the flexor tendon of the great toe, was a dark purple patch, roughly oblong in shape, three-quarters by a half inch in size and considerably raised above the level of the surrounding skin. The edges were sharply defined, the surface rough and hard to the touch, simulating an ordinary callosity.

On the dorsum of the right foot, over the tendon of the fourth toe, was a faint, dark blue, flattened papule, considerably infiltrated and deeply imbedded in the surrounding tissue.

Finally, there were two faintly defined, dark blue, penny sized plaques on the ball of the sole of the right foot, visible only on close scrutiny, and presenting no palpable differences in consistence from the neighboring keratotic skin. Pressure on these elicited no pain; in fact, the patient was not aware of their existence.

A tentative diagnosis of hemorrhagic multiple sarcoma of Kaposi was made. A few days later, Dr. Fordyce examined the patient and confirmed the diagnosis.

Histopathology.—For purposes of microscopic study, the split-pea sized nodule below the left eyelid was ablated under cocaine anesthesia and the small papular lesion on the right forearm was removed by the cutaneous punch. Sections were prepared and stained by the usual methods.

Nodule from the face. With the exception of a moderate grade of edema of the basal cell layer and a widening of the intercellular spaces of the rete cells, the epidermis showed no changes. Nor was there any increase in pigment granules. The papillæ were flattened from pressure exerted from below. In the pars papillaris a narrow, subepidermal band, faintly stained, showed a pronounced edema with granular degeneration of the collagen. Below this degenerated zone and extending down to the subcutaneous tissue was a dense connective tissue structure, the most prominent feature of which was the large number of new formed blood vessels and lymph spaces, lying within compact masses of fusiform cells and aggregations of small round cells, the latter uniform in size and possessing large, deeply stained nuclei. These round cell masses were located chiefly in the upper portion of the cutis. The fusiform or spindle shaped cells appeared as oblique, longitudinal and transverse bundles, situated mainly in the lower portion of the corium. Immediately adjoining the subcutaneous areolar tissue, these fusiform cells were arranged in the shape of more or less circumscribed nodules, resulting from their whorl-like disposition around a central point, usually formed by a group of numerous small blood vessels. Many of the blood vessels showed marked endothelial proliferation, resulting in partial obliteration of their lumina. In many places spindle shaped endothelial cells were seen to have their starting point in the intima of the blood vessels. There was considerable blood extravasation and deposition of blood pigment throughout the collagen. Here and there mitotic figures were seen, scattered among the fusiform cells. Many of the vessels were engorged with blood cells. As a result of the cell infiltration of the new growth, very little remained of the collagenous tissue throughout the corium.

Fig. 2.—Idiopathic hemorrhagic multiple sarcoma of the skin (Kaposi). Showing the raised and infiltrated plague over the flexor tendon of the great toe.

Papule from right forearm. The changes observed here were in every way similar to those above described, with the exception that the increase in blood vessels and lymph spaces was not at all marked, the duration of this lesion being much shorter, while the collagen was far more plentiful than in the older lesion.

This histopathological structure corresponds to the many descriptions of tissue sections derived from cases of Kaposi's multiple hemorrhagic sarcoma, conforming in its type to the round and spindle celled angiosarcoma.

Recapitulating, we have before us a dermatosis presenting a few widely scattered, irregularly distributed, painless, bluish and purplish macules, nodules and plaques, which disturb the patient only from the cosmetic point of view. The aggregate area of affected integument is scarcely extensive enough to cover the surface of a silver dollar. The problem is to interpret these manifestations from a clinical standpoint, if that is feasible; that is, to diagnosticate the eruption by means of inspection, palpation, the patient's history, etc., instead of relying solely upon the laboratory findings. As has been hinted, the permission to remove pieces of tissue for microscopic examination being as often refused as granted, the question of obtaining biopsy material frequently is dependent upon the intelligence, courage or caprice of the patient. The great value of clinical diagnosis in the obscure dermatoses must not be underrated.

Without entering into the technicalities of differential diagnosis, it should be said that, aside from the idiopathic multiple sarcoma of Kaposi, two other conditions were considered; namely, the multiple benign sarcoid of Boeck, and dermatomyoma. In various ways these two rare dermatoses bore resemblances to the eruption in our case. The weight of evidence, however, favored Kaposi's sarcoma, on the following grounds: (1) the typical distribution of the lesions on the exteremities and face; (2) the absence of pain; (3) slow growth; (4) the reddish blue and purple color; (5) the firm consistence of the nodules; (6) the blanching of one of the lesions under pressure with a piece of glass, suggesting its angioma-like structure. It will be seen that the primary diagnostic factors mentioned above—namely, the distribution of the lesions as a whole and the character of the individual lesions—both play important parts in the determination of the nature of the disease.

In its *advanced* stages the idiopathic hemorrhagic multiple sarcoma of Kaposi presents a clinical picture so striking and characteristic that the diagnosis is readily made, by the trained observer, at a glance. The distribution of the lesions, their color, consistence, configuration, mode of progression, etc., at once serve to identify the disease. The excellent descriptions and illustrations of the affection in our American text books and in numerous monographs obviates the need of taking up space here with a detailed account of the malady. The important point to bear in mind is that in its tendency to cause death by visceral metastases it resembles true sarcoma, and that early diagnosis and prompt treatment may save the life of the patient.

The majority of these patients present themselves at the clinics with the disease already involving extensive areas of the skin of the upper and lower extremities, and in whom the process had been steadily advancing for months and years. In some cases internal metastases have already taken place, and the most that can be offered them is palliative treatment. In the earlier stages the disease is almost free from subjective sensations; itching and burning may be present in a moderate degree. Later, the patients may complain of stiffness of the joints in the hands and feet, due to the edema and infiltration of the affected skin. Thus these patients frequently neglect themselves until the disease is well advanced and the more serious symptoms of pain, tenderness, and interference with the muscular functions begin to make their appearance.

It is a singular fact that the cases seen in New York almost invariably occur in men of Galician and Italian birth. The Neapolitan dermatologist, De Amicis, has seen more than fifty cases, all in males. The occurrence of the disease in the female sex has been recorded in only five instances out of seventy-three cases in the literature, according to Sequeira and Bulloch.[1] Initial efflorescences on the cheeks and nose have been recorded by Perrin[2] and by Funk.[3] The disease advances steadily, fresh macular, nodular, and tumor-like growths, some of which may later ulcerate, appearing progressively; in some cases the lesions involute spontaneously in one area, to appear in new forms elsewhere. Sometimes the mucosæ are also attacked by the process. According to Kaposi the average duration of the disease is four years. Cases of twenty-five years' duration have, however, been reported. In 1905 the writer had occasion to treat a patient, a Galician Jew, afflicted with the disease, in whom the first symptoms manifested themselves fifteen years before. The skin of the extremities was very extensively involved. He died of metastases and inanition about three years later, despite the fact that *x*-ray treatment had succeeded in causing a partial disappearance of the cutaneous manifestations of the disease. The affection usually appears between the fourth and sixth decades. Nothing is known as to its etiology.

Prognosis and Treatment.—In cases where the eruption consists of a few scattered and isolated nodules and plaques, operative treatment is certainly indicated. The nodules which were surgically removed in the patient here recorded have thus far shown no signs of recurrence, although too short an interval of time has elapsed to justify any definite opinion on the advisability of using the knife in these cases. We must always be on guard against the possible dissemination of the lesions when having recourse to surgical measures.

Several cases are recorded in which the use of arsenic, in various forms, has resulted in apparent cures and many cases have been benefited by the drug, administered by mouth and by injections.

Treatment with *x*-rays offers the best means of combating the disease, especially in its early stages. Under massive-dose exposures the lesions melt away quite readily, leaving hardly anything more than a faint stain to mark the site of the plaque or nodule. Recurrences are apt to take place, but these also subside under the influence of the *x*-ray. The combined use of radiotherapy and arsenic would seem to be the most rational course to follow in the treatment of the disease.

Such a plan of treatment is under way in our patient. He was particularly anxious to get rid of the patch on his nose and was given two Holzknecht units of *x*-ray, using a No. 9 Benoist tube. Nothing is left to mark the site of the lesion, excepting a faint reddish discoloration, which promises to fade entirely. It may not be too much to look forward to a complete arrest of the malady in his case.

AMPUTATION OF THE GREAT TOE, WITH REMARKS ON THE MUSCULAR PHYSIOLOGY OF THE LOWER EXTREMITY.*

By JOHN C. SCHAPPS, M.D.,

BUTTE, MONTANA.

In walking, the front part of one foot, fixed on the ground while the heel and the whole of the other foot are raised forms a working base and tendon anchorage to which the superjacent parts are adjusted and upon which the whole body is supported and moved. Of this base, the great toe constitutes the most important part. It has its own muscular system, the tendons of the other toes being divisions

From a photograph showing the foot supporting the entire weight of the body.

leading to muscles common to all four. From the distal phalanx of the great toe run two strong tendons, one back over the foot and through the annular ligament of the ankle where it turns sharply upward to reach its muscle on the front of the leg, the other passing back under the foot, across the arch like the string of a bow or the tie-rod of a truss and turning around a bony projection at the inner side of the ankle to reach its muscle on the back of the leg. The turning points are virtually pulleys resting on the tendons anchored in the great toe, traction upon the tendon raises the ankle in a sling, and under the body weight, the back part of the foot, carrying the leg, slides down the tendons toward the front and the arch increases in concavity.

The two muscles are known as extensor and flexor of the great toe. But their function is obviously not to move the toe in relation to the leg—a perfectly useless performance—but to move the, movable, leg in relation to the fixed toe. In fact, in studying the lower extremity as an organ of locomotion one finds that the still accepted teaching regarding its muscular physiology needs not to be revised merely but to be reversed—that, in general, muscles do not act from proximal parts upon distal, as their names indicate, and as do those of the upper extremity, but from below upward. Or when they do act from a superior upon an inferior part, the superior point must be fixed in adjustment to the working base by muscles acting from below upward. All, or nearly all, of which was presented twenty-five years ago by Thomas S. Ellis of Gloucester, England, in a valuable little work, "The Human Foot" (William Wood & Co., New York).

Rising on the ball of the foot is supposed to be effected by the upward pull of the tendo Achillis muscles on the point of the heel. Were the foot a solid bone from heel to toe, and had the muscles a fixed point above from which to act, they could, independently, perform this function. But transverse joints through the tarsus, between the tarsal and the metatarsal bones, and between the metatarsal bones and the phalanges, divide the foot into segments, and upward traction on the heel while the toes are against the ground would result simply in depression of the middle of the foot were not the segments kept in their normal arched relation, which is done principally by the muscles whose tendons lead from the great toe as described. They enter also into all adjustments of the leg to the foot, and thus help to provide the point of resistance for such muscles as the anterior tibial, which apparently does act from above downward and possibly for the heel cord muscles. But paralysis of the heel cord group does not prevent the subject from rising on the toes, which would indicate that the important function of these powerful muscles is not to raise the heel.

A true conception of the mechanism of walking is of fundamental importance in dealing with all mechanical disabilities of the lower extremity. But confining our attention now to the muscles whose tendons are anchored in the great toe, we find that they take part in raising the heel, maintaining the integrity of the foot and providing a point for muscles to act from the leg upon the foot. It occurred to me that the severe disability accompanying the loss of the toe is due to cutting loose the muscles, and might be avoided by saving the tendons and uniting them over the end of the metatarsal bone. November 27, 1914, Dr. P. H. McCarthy of Butte, Montana, adopted my suggestion in the case of a young woman whose toe he removed for sarcoma of the distal phalanx, and permitted me to take part in the operation. The end of the metatarsal bone was denuded, the tendons drawn taut overlapped for an inch or more on the dorsum and were sewn together with chromicized catgut. (It would possibly have been better to have split the thicker tendon and inserted the thinner.) The dressed foot was bandaged to a board with a pad under the instep, and the patient not permitted to stand on it for six weeks. The result is highly gratifying. She has a perfect arch even under the entire body weight with the heel raised, as shown by the accompanying photograph which was taken six months after the operation, and walks without perceptible limp.

Owsley Block.

*Read at annual meeting of the Medical Association of Montana, Bozeman, Mont., July 15, 1915.

A SINGLE STITCH APPENDECTOMY.

PRELIMINARY REPORT.

By W. FRANK FOWLER, M.D.,

ROCHESTER, N. Y.

A PAPER by Dickinson,[1] in which he made an appeal for efficiency engineering in pelvic surgery, stimulated my interest in a single stitch operation. My excuse for adding this method of appendix removal to the countless existing modifications of technique is that it appeals to me as being simple, easy, and expeditious. The operation is much more easily and quickly done than its description would indicate.

Description of the Author's Clamp.—A 7¼-inch curved Pean hysterectomy forceps with longitudinal grooves was bent to approximate a 45-degree angle with a rounded shoulder, leaving a straight arm at the end of about 1 5/10 cm. A similar forceps 6½ inches long is also useful but not essential. The

FIG. 1.—Fowler appendectomy clamp.

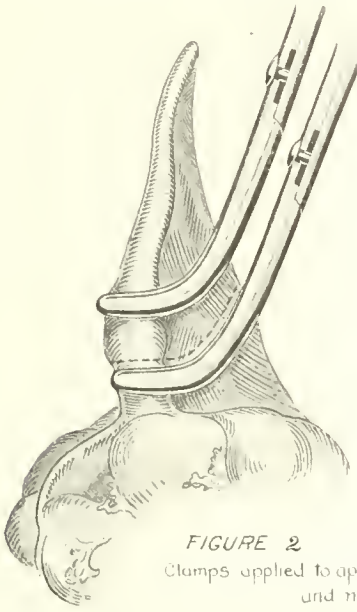

FIGURE 2

Clamps applied to appendix and mesoappendix

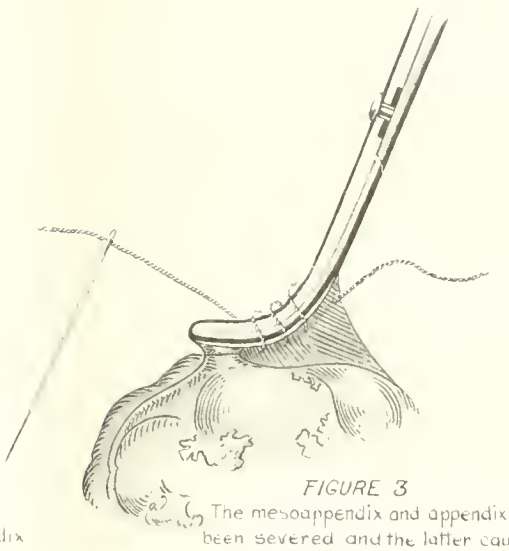

FIGURE 3

The mesoappendix and appendix have been severed and the latter cauterized, the appendix tied off beneath the clamp, and the suture-ligature on the mesoappendix placed.

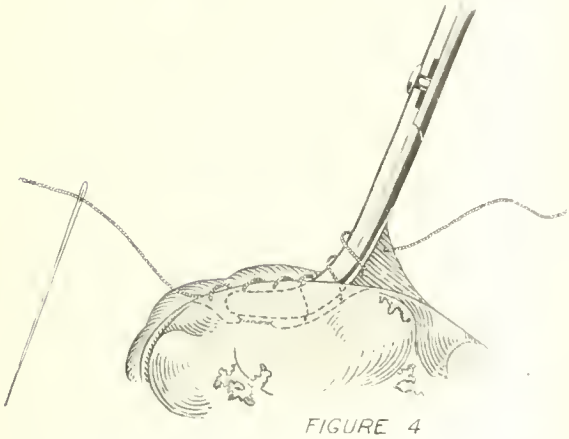

FIGURE 4

The appendix stump has been invaginated by depressing the clamp. The Lembert stitches uniting the caecum over the stump are placed. These complete the suture.

FIGURE 5

The clamp has been withdrawn and both ends of the suture are held taut.

FIGURE 6

The mesoappendix and bowel ends of the suture are tied together completing the operation.

V.E. Klippert. '15

instrument was made for me by the R. J. Strasenburgh Co., Rochester, N. Y.

The *steps of the operation* are as follows:

1. Two clamps are applied, one to the base of the appendix and to the mesoappendix about 3 10 cm. from the cecum; the other parallel to and close above the first. Small curved broad ligament clamps may be used, but the special instrument is more convenient. Close the instrument tight in order to hold the mesoappendix securely.

2. The mesoappendix and appendix are severed between the clamps close to the lower one, preferably with a scalpel, and the appendix stump is touched with carbolic and alcohol.

3. A straight round intestinal needle, conveniently 4 5 10 to 5 cm. long threaded with a number two catgut, or permanent material if desired, is passed through the mesoappendix beneath the clamp and close to the appendix. The appendix is tied off and both ends of the ligature cut short.

4. Stitches with the same needle and suture are passed through the mesoappendix and around the clamp from the outer border to the appendix. Three or four turns about the clamp are usually sufficient. These stitches are taken after the manner of securing the broad ligament in salpingectomy. (In Figs. 3 and 4 these stitches should extend to the appendix.)

5. Downward pressure is made on the clamp which depresses the appendix stump and allows the cecum to fall together over it. The appendix stump is permanently buried by suturing the approximated bowel surfaces with a few Lembert stitches, using the same needle and suture as in step four.

6. Traction is maintained upon the bowel end of the suture while the clamp is withdrawn through the loops on the mesoappendix.

7. The first or mesoappendix end of the suture is drawn tight and is tied securely to the bowel end.

With a single stitch and one knot (exclusive of the tie on the appendix) we have buried the appendix stump as with a purse string, secured the mesoappendix and tied it down to the cecum over the appendix site.

Modifications of this procedure will suggest themselves to meet varying conditions. For illustration: If the appendix tip is kinked down so there is room only for the application of one clamp to the mesoappendix we may dispense with the upper one and secure the distal end of the appendix in the usual manner.

The method of burying the stump is somewhat similar to the suture of Bartlett.[2] The entire procedure might be considered a modification of the Mayo operation.

Auscultation of the Venous Pulse.—M. O. Josué describes a method for this purpose which he believes gives results equally as good as those obtained with the polygraph. The technique is as follows: The bell, 2 centimeters in diameter, of a monaural stethoscope is placed at the base of the neck of the patient between the sternal and clavicular divisions of the sternocleidomastoid muscle, and as near the clavicle as possible. The direction of the stethoscope should be toward the mediastinum. The venous murmurs heard correspond to the elevations in the polygraph tracings.—*Presse Médicale.*

NEURITIS, THE MODERN AMERICAN DISEASE.

By T. McCALL ANDERSON, M.D., L.M.S., ENG.

ASSISTANT IN CLINICAL MEDICINE, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THERE is probably no disease which is so universal, so little understood, so unsatisfactory in its response to purely medical treatment, as neuritis. The very fact that so many therapeutic measures have been employed from time to time, and that so many methods of treatment are advocated by members of the medical profession, proves that up to the present time we have been more or less at a disadvantage in the handling of this most distressing condition.

For the past year I have studied this disease from every angle, with the object of discovering not only the pathological lesions, but also the means of putting its treatment on a rational basis, and the results of my investigation have been so remarkable, and the treatment so successful, that I am writing this article in the hope of stimulating discussion and further investigation, so that in the future we may have confidence that we are dealing with a disease which responds satisfactorily to rational therapeutic effort.

There were two things which struck me early in my experience. First, the variety of the symptoms, and second, the great number of patients who thought their trouble rheumatism, and who had been treated for rheumatism, often for years. As I began to gain a more accurate conception, however, I found that in neuritis the pain was caused mostly by muscular spasm of contraction, while in rheumatism it was due to congestion or true inflammation, with or without actual tissue change. This being the case, it follows that the pain in neuritis is much easier to relieve than that of rheumatism, because, while the name neuritis means nerve-inflammation, in practice the patient nearly always seeks relief before actual inflammation and resulting tissue-change in the nerve structure have occurred. In order for the nerves to become irritated sufficiently to induce spasm or contraction, powerful influences must have been at work for some time, the principal being a lowering of vitality from overwork or nerve-strain, and toxemia, usually intestinal in origin, although any toxin, such as alcohol or the mineral poisons, may induce the symptom-complex. From these preliminary remarks the reader will have grasped three essential points, namely, that in a typical neuritis we usually have nerve-strain or nerve-exhaustion and toxemia, together with contraction of muscular tissue from the action of the toxins generated by exhaustion, or more directly by absorption from the blood-stream.

Let us now consider the principal symptoms complained of by the patient. There is usually a feeling of tiredness in the arms or lower extremities, the patient frequently complaining that the hands have gone to sleep. There is pain, or at least tenderness, in the neck, back, or shoulders, with headache in many cases. The patient feels weak and in poor general condition, becoming exhausted by the least exertion, mental or physical. The business man finds it hard to concentrate, the society girl is unequal to fulfilling her social obligations. In many cases there is marked constipation, though occasionally diarrhea may occur, representing Nature's effort at elimination of the toxins. Loss of

sleep is frequent, especially in the cases where there are bad contractions or congestions in the upper cervical region. In the intestinal types there is quite often a failure of response to cathartics. This is due to the fact that the muscular walls of the bowel share in the exhaustion and become atonic owing to neuritis of the nerves supplying the involuntary muscular fibers, on the good condition of which adequate peristalsis is dependent.

But there are certain definite areas where contraction in neuritis and congestion in rheumatoid neuritis are most frequently found. There is usually pain on deep pressure or deep massage applied over the nerves radiating from the cervical plexus in the substance of the sternocleidomastoid muscle. There is also very commonly pain on pressure about an inch below the occipital protuberances and slightly toward the median line. Another area of tenderness often exists in the erector spinæ muscles below the level of the seventh cervical vertebra. In the cases where the neuritis is mostly abdominal, particularly where the intestinal toxemia causing it is produced by some surgical condition such as adhesions in the region of the ileocecal valve, there is an area of tenderness in the dorsal region at the level of the tenth dorsal vertebra, and electrical reaction is frequently poor at this point, especially in cases complicated by gastric ulcer or adhesions in the region of the stomach—a phenomenon readily explainable when we consider the connection of the sympathetic nerve with the solar plexus. In regard to this last remark, I would point out that the ability of the patient to stand a much stronger current over this region of the spine is a valuable aid in the diagnosis of abdominal trouble, as I have repeatedly verified by use of the *x*-ray and seen confirmed on operation.

In the cases whose symptoms consist of pain in the limbs, tender areas with extreme sensitiveness to electricity are found in the lumbar and sacral regions, the pain radiating down the sciatic or anterior crural nerves, with definite areas of congestion or contraction in the buttocks, at the sides of the knees, or in the substance of the gastrocnemius muscle. Numerous other symptoms might be enumerated, but I have called attention to the most common, and have also shown the infinite variety of the symptoms which may be encountered in this disease, different cases varying according to the location and cause of the nerve-toxemia producing them.

Having done this, let us consider the means for their relief. No treatment will be curative which does not aim at the removal of the underlying cause, be this a congested liver, a sluggish intestine, a nerve-toxemia from overwork, or abdominal adhesions interfering with peristalsis. There is no routine treatment, each case having to be handled according to the causative factor. To cases due to some surgical complication I shall not here refer. The largest class includes those associated with intestinal toxemia. In these the first indication is thoroughly to clean out the bowel, doing this slowly so as to avoid exhaustion and consequent locking up of elimination. In this connection I would like to say a word as to the method employed. At least a week is spent in the process of detoxication, telling the patient to drink as much hot water as possible the first day. A pill is then given containing calomel, cascara, rhubarb, and atropine. This should be followed in the morning with a saline. Strychnine may now be commenced for its effect on the the unstriped muscular fibers of the intestine, giving from 1/60 to 1/30 grain two or three times a day before meals, grading the size of the dose according to the individual case. The second day allow a rest from catharsis. On the following night 10 grains of blue mass or from 2 to 4 grains of calomel is given; if the lower dose of the latter is employed it should be given fractionally and followed as before with a saline. Then another day's rest, and on the succeeding night 1/8 grain of podophyllin repeated in an hour and followed in the morning with a saline series, such as a dram of milk of magnesia, repeated every hour for three or four doses. This treatment, varied in certain cases by high colonic irrigations, constitutes the cathartic or detoxicating treatment. In patients whose heart-muscle has been weakened by the toxemia, a complication by no means uncommon, excellent results often follow the use of sparteine in doses of from 1 to 3 grains by mouth three times a day.

For the actual relief of pain, effected by removal of contractions and congestions, the following method is employed, for assistance in evolving which I am indebted to Mr. Joseph Jeiter, who has cooperated with me in evolving the procedure here advocated. Having determined the areas of contraction or tenderness by thorough and deep exploration with the fingers and massage of the muscles, one electrode is placed under the abdomen and the other over the area involved. The secondary faradic current is then applied, beginning very gently and increasing to the point at which the patient can comfortably bear it. During the application of the current the electrode is moved over the affected surface with an ironing motion. After a course of such treatment, lasting for from ten to fifteen minutes, the current is shut off and the part is massaged deeply, when in many cases nearly all pain will be found to have disappeared. Each spot of contraction or tenderness is similarly treated on this or subsequent occasions, special care being devoted to the abdomen where the most obstinate contractions frequently exist. After a few such treatments the patient should feel much relieved, and the most obstinate cases are generally very much benefited in the course of three months, always excepting those due to some surgical complication or those where actual tissue-change or paralysis has occurred, though even these are generally much improved. Of course the success of the treatment depends on the ability of the physician to diagnose the spots of tenderness, and on the ability of the electrotherapeutist to carry out his part of the treatment, an ability, however, which readily comes with practice.

15 WEST FIFTY-FIFTH STREET.

THE TREATMENT OF GALLSTONE DISEASE.

BY OTTO LERCH, A.M., M.D., PH.D.,

NEW ORLEANS, LA.

PROFESSOR OF MEDICAL DIAGNOSIS AND TREATMENT AT TULANE UNIVERSITY, POST-GRADUATE DEPARTMENT

BILIARY calculi consist of cholesterin and lime; the former is excreted by the epithelium of the mucous membrane of the gall-bladder and the latter is a normal ingredient of mucus. A duodenal catarrh may advance into ducts and gall-bladder, bacilli may enter them and cause precipitates; but as long as the bladder functions well and the bile flows freely, the thrown-off epithelium, the mucus, the bacteria,

and the precipitates will be readily and completely removed.

Retention of bile and its decomposition is the primary cause of stone formations, though some degree of stasis is physiological, due to the powerful sphincter of the papilla, which permits the filling of the gall-bladder.

Gallstones may develop in an aseptic stagnating bile, due to decomposition. Infection may take place and cause the formation of new stones and an increase in size of those already formed. Conditions may change and often do so, bile commences to flow again, the inflammatory process passes, and the bearer of the stones may go through life unconscious of the calculi he carries in his gall-bladder. Gallstones are seldom found in young adult life, though they are occasionally met with in childhood. Not more than from 1 to 3 per cent. up to thirty years of age, 7 to 11 per cent. from thirty to fifty years, and 15 to 20 per cent. in the aged. A large number of these have never shown symptoms of liver or gallstone disease during life, the stones being discovered at autopsy after the bearer has died of some other disease.

The colic brought on by a moving calculus or inflammation is usually the first symptom indicating the presence of stones.

In a number of cases the diagnosis is readily made. The colic with pain over epigastrium or gall-bladder, jaundice, fever, bile in the urine, and alchoholic stools when a stone passes or has passed through the common duct into the duodenum, the large liver with smooth border, a stone or stones found in the dejections, and occasionally the Roentgen rays leave no doubt as to the nature of the trouble.

Stones passing one after another from the cystic into the common duct and occasionally a mucous plug or clot after a stone has passed, may cause repeated attacks, accompanied by continued jaundice, fever, and chills, due to an invasion of colon bacilli and pus bacteria. If the stone remains in the bladder icterus is usually absent, or if present, it is due to inflammation caused by invasion of colon bacilli and to pressure upon the common duct. A distended gall-bladder frequently visible, readily percussed and palpated with light percussion and light palpation, colics, or in mild cases only pain in the back and epigastrium, fever, and the sudden onset of the attack make the diagnosis in these cases. It is occasionally mistaken for ulcer of the stomach, appendicitis, or ileus, the nearness of the pyloric orifice and gall-bladder, muscular rigidity over the appendix region, and the colics making such mistakes possible. The first question that arises when a diagnosis of gallstones has been made, is whether an operation is necessary, and whether that has to be immediately done to protect the patient.

The views on this subject differ widely between internist and surgeons, and even between the surgeons they are largely at variance.

Some advise in all cases of biliary calculi an immediate operation, allowing only a small percentage to be treated by medical methods; others advise, and this seems to be the majority, that only a small percentage of gallstone patients should be operated upon.

Kahr operated only on 1300 of 4000 patients that consulted him for gallstones, and comes to the conclusion that only 20 per cent. of patients suffering from gallstone disease ought to be operated upon, and he is a decided opponent of an early operation during the first attack. The following table published by this author in 1909 and quoted by Lehnhartz, is of great interest:

Death rate, 1904-1909, at the Surgical Clinic of Heidelberg; Pure-stone cases, 4 per cent.; benign simple cases, 11.3 per cent.

Mayo Brothers, in 845 cystotomies, 2.3 per cent.; in 319 ectomies, 3.43 per cent.

Koerte, 327 simple cholelithiasis, 238 pus and choledochus stone, 21 with simple complications, 10 per cent.

Borelius, 50 cystectomies, none.

Surgical Clinic University of Giessen, 513 pure-stone cases, 9 per cent.; 46 with simple complications, 8.69 per cent.

Kocher, 103 pure-stone cases, 2 per cent.

Kuemmel, 169 pure-stone cases, 4.7 per cent.; 14 with simple complications, 14.3 per cent.

Kehr, 238 pure-stone cases, 2.9 per cent.; 73 with simple complications, 20 per cent.

The Mayo Brothers had a death rate in 207 choledochus operations: 105 without pressing symptoms, 2.9 per cent.; 61 with fever, chills, and jaundice, 16 per cent.; complete occulusion of common duct, 34 per cent.

Relapses with colics due to stones or adhesions have been reported by a number of observers.

In 1911, the Mayo Brothers published 4000 operations for cholelithiasis with a mortality of 2.75 per cent. In 2920 operations the disease was confined to bladder and cystic duct, mortality 1.8 per cent. In 2165 of cystotomy, mortality 2.4 per cent., and in 492 operations involving the common duct, mortality 8 per cent. In operations during quiescent state, 3 per cent.; with jaundice, 10 per cent., and with complete obstructive jaundice, 25 per cent.

It is also of interest that they found in 1244 operations for uterine myoma that 7.15 per cent. had gallstones. Dr. Fossier who has collected the cases from the records of the Charity Hospital of New Orleans for me from 1906 to 1914 found in 96 operations for cholelithiasis mortality 21.5 per cent. In 58 cases treated medically during the same time, mortality none.

Lenhartz* in his article on the treatment of the diseases of gall-bladder and ducts, in which he also discusses the indications for an operation, quotes statistics of the Eppendorfer Hospital and finds that from 109,700 patients treated from 1902 to 1908 only 515 suffered from liver or gallstone disease, exclusive of cirrhosis, and that of 1800 autopsies death was due in only 6.7 per cent to gallstones and in 72, or 0.4 per cent., to carcinoma of the gall-bladder.

From his own practice he reports 10 to 12 deaths caused by diseases of liver and gallstones from 10,000 to 13,000 patients, many of whom had passed through the surgical ward. Cause of death severe cholangitis and cholecystitis and septic pylephlebitis. He often saw most severe cases with chills and high fever recover, even with colon bacilli in the blood, if not operated upon.

Kohnheim advises not to operate till all medical treatment has failed.

I believe it is advisable to call a consulting surgeon early so as not to miss the time when an operation may become necessary.

If a stone lodges in the cystic duct, causing colics

*H. Lehnhartz-Behandlung d. Erkrankung der Gallenwege Handbuch d. gesamten Therapie, Vol. II, p. 703.

and swelling of the gall-bladder, an operation would prevent a closure of the common duct, but as it is in the experience of every physician that such stones frequently pass under treatment, leaving the patient in perfect health during the remainder of his life, an early operation in this case has not been adopted generally. In repeated attacks with renewed inflammation of the gall-bladder, physician and surgeon have to decide whether an operation is advisable. The prognosis is better if the patient is operated upon between attacks, when free of fever and with reduced inflammation. In cases with severe general infection, repeated attacks with chills and fever, especially when chronic inflammation has produced a thickened and shrunken gall-bladder, an operation is indicated, unless disease of the heart or a weak heart and a depressed general condition contraindicate the operation.

If a stone closes the common duct, it is better to wait, unless the duration of the trouble, the general condition, and the wish of the patient call for an earlier operation. *Jaundice makes the prognosis more grave.*

The treatment of the biliary colic is clearly indicated. Pain has to be stopped, the expulsion of the stone favored, inflammation subdued, and the strength of the patient supported. Morphine is a supreme remedy to stop pain, and it is best given subcutaneously. The dose should be sufficiently large to be effective. It relaxes the contracted muscles that hold the stone, the bile can flow again and push the stone onward, till the effect of the remedy ceases, a new cramp occurs, and severe pain calls for another injection, preventing injury and necrosis due to pressure. The treatment has to be repeated until the stone has passed into the duodenum.

Atropine acts in a similar way by relaxing muscular spasms, and can be given alone or in combination with morphine. It influences the inflammatory process by first contracting and then dilating the arterioles, relieving congestion. It can be given to dryness of mouth and throat and dilatation of the pupils. Opium and belladonna suppositories occasionally stop the pain. Chloroform inhalations are dangerous and have been entirely abandoned by most practitioners.

Pyramidon, antipyrin, and other coal-tar preparations do not stop the pain of severe paroxysms but often give satisfactory results in milder attacks. The salicylates in large doses are occasionally useful. Of the physiological measures of treatment rest in the recumbent posture is of paramount importance. The excruciating pain forces the patient to go to bed, and this meets the first and most necessary condition to relieve muscular spasms. Though not sufficient to stop the pain, it favors the action of other measures. Mental rest is almost of equal importance, excitement and emotion being often the cause of a paroxysm. A well-ventilated, half-darkened room and a cheerful and quiet nurse will accomplish much. Rest, physical and mental, is the most important remedy to influence beneficially the circulation. Congestions are relieved and the blood flows with ease and in abundance to diseased structures where the current is slowed and retained in the inflammed area by injured vessels. The next in importance to assist the action of drugs and of rest is heat. It may be administered as a full hot bath, as a sitz bath, in the form of poultices and cataplasms, or as electric thermophore.

If heat is applied, dilatation of vessels and reddening of the skin occur at once and gradually become more intense. The application of great heat will cause immediate paling followed by reddening, and this persists for some time after the application has been removed.

Cold acts in a similar way, and an ice-bag may be used when heat is not well borne. The direct effect of cold upon the vasomotor nerves produces a narrowing of the vessels and muscular contraction. This is followed by dilatation of the vessels and reddening of the skin, which becomes finally cyanotic when the application is not removed.

With either method we stop pain by paralysing the sensory nerves and we produce an active hyperemia by influencing the vasomotor apparatus.

Electricity is recommended and occasionally useful. It stops pain and causes an active hyperemia. Massage, when skilfully given, will produce hyperemia, ease pain, and favor the expulsion of the stone or stones. It will prove of advantage only in the hands of a physician who is thoroughly familiar with the method. Unskilful application may do great harm and cause rupture of the gall-bladder. The patient has to be carefully watched during the paroxysms, and especially the aged need analoptica like coffee, tea, strychnine and alcohol in some form. Death has been produced by shock during a paroxysm. A morphine and atropine injection relieves the cramp and will best prevent shock.

The treatment of gallstone disease is indicated by its etiology, pathology, and course. The presence of an inherited predisposition and the facts that it is only exceptionally found in childhood, rarely in the young, that it becomes more frequent with advancing years and its great predominance in women, allow of but one explanation—a poor abdominal circulation. The inherited predisposition is enteroptosis with its pendulous abdomen and relaxed abdomnnal walls or rigid recti and diastasis; the greater frequency increasing with years is due to the adoption of an indoor life and late hours, with usually a more generous diet to burden the circulation; the greater frequency in women is due to an indoor life as well as to the relaxation of the abdominal muscles after childbirth and to lacing, which interferes with diaphragmatic breathing. *A pure and free flowing bile prevents the formation of stones and dissolves them after they have been formed—this is the only solvent of biliary calculi so far found.*

Frerichs and others found calculi small and crumbling after treatment. I can confirm this observation.

Mr. T., 52 years of age, a civil engineer. He gives a history of renal colics during which he passed gravel and calculi the size of a small pea. He was to be operated upon for stone in left kidney, when the pains stopped suddenly after he had passed some blood and mucus. He has not had symptoms of gravel or renal calculi for 7 years. Early in 1912 he had his first typical gallstone colic, followed by five others up to February, 1913. At that time he called on me. He was deeply jaundiced and had chills and fever. Under treatment all symptoms passed, but were followed by another attack a few months later. Dr. Fossier, who treated him in my absence advised an operation. A gall-bladder with thickened walls was removed which contained two very friable small stones, the size of a pea, breaking readily on touch.

Mrs. P., 43 years of age, mother of eight children. Patient had a typical gallstone attack nine years ago, followed by three others four years later. Then she was in perfect health till April, 1913, when she was seized with another colic. I saw her during this attack. She was deeply jaundiced and had fever and chills. All symptoms passed and she then returned to her

home in the country, but did not continue the treatment. Eighteen months later she came back to me with another severe attack with chills, jaundice and fevers. As before the symptoms passed with the exception of occasional sharp pains in the pit of stomach. I advised operation, which was done, and two small very friable stones, the size of a pea, were found in the gall-bladder.

I have treated a large number of patients with gallstone disease and only a few had to be operated upon. The findings in these showed that medical treatment may be curative. Naunyn has shown that calculi inserted into the gall-bladder of a dog are dissolved within two months. A pure free-flowing bile is possible only when the abdominal circulation is in good condition, and our therapeutic measures must be directed to produce this. A bandage is necessary in almost every case to narrow the abdominal cavity and give counter pressure to diaphragmatic breathing. It is a substitute for muscles. I have previously described a bandage designed by me for this purpose.

Every healthy outdoor exercise tends to improve the general circulation, and as a part of it the abdominal circulation, if it is not overdone. Too much of it is injurious; it must be taken short of fatigue and exhaustion. The means that have developed the organism under constantly changing and adverse condition in the evolution of the race are the best to preserve it. Exercise is one of them—golf, tennis, borseback riding, walking, swimming, rowing, gardening, etc. Of room exercises those are to be directed that press upon the abdomen. Bending forward, going into the knee position, vigorous moving and pressing of the thighs against the abdomen, lying or standing. Whatever exercise is directed must be combined with deep breathing, and must be selected to favor the respiration.

Deep, methodical, and slow inspiration and expiration exert a forceful pressure upon the liver and all abdominal contents, and expand the chest. Exercise ought to be taken on an empty stomach or at least two or three hours after a meal.

Rest is of no less importance in the prevention and treatment of diseases of the liver than is exercise. Blood drops into the abdominal cavity when the upright position, sitting or standing, is kept up too long. Heart and vessels tire and congestion of the abdominal organs is the consequence. This is aggravated in a southern climate in which the surface vessels have to dilate to give off surplus heat and keep the body temperature normal. As with other therapeutic measures we have to individualize, in most cases one hour of rest in bed after the mid-day meal and an early bedtime are sufficient. A suitable diet is of no less importance than exercise or rest, and the literature on this subject is voluminous.

Some advise a vegetable, others a meat diet, and others again a mixed diet. Bile has no digestive action on carbohydrates, though it has to be remembered that when taken in excess the latter gives rise to intestinal fermentation. Neither has bile an influence on meat digestion, but when intestinal putrefaction is great, it is useless to give meat. Experiments on dogs have shown that a pure meat diet increases the flow of bile. Yet a vegetable diet is preferred by most observers, because the antiseptic function of the liver suffers in gallstone disease and ptomaines and toxins are ingested with a meat diet. Alcoholics, tea, coffee, and condiments have to be avoided for the same reason. Fat must be greatly reduced in quantity. The gray fatty stools when the common duct is closed prove that the absorption of fat is impaired. A vegetable diet has the further advantage of tending to produce regular bowel evacutions. Constipation favors the retention of bile.

The acute attacks require a liquid diet. The principle to save the liver from further injury is the most important consideration. During the acute attacks of cholelithiasis and cholecystitis little attention need be paid to the nutritive value of the food, for the attacks are as a rule of short duration. Frequent and small meals should be served to encourage the flow of bile. *The passing of chyme stimulates the papilla to open and discharge bile into the duodenum, and this is by far the best cholagogue we possess.* Warm and hot drinks are soothing; cold drinks may cause severe cramps. The ingestion of a large quantity of water has no direct influence on bile secretion. Small amounts of fat, especially when given emulsified, as milk, butter and cream, may be allowed unless the pancreatic function is completely destroyed. Carbohydrates are of value and may be given as toast, malted milk, milk soups, with grits, purées of tender vegetables, and fruit juices. Meat simply prepared is not injurious, if intestinal putrefaction does not make it so. A moderate amount of albumin and fat with somewhat larger quantities of carbohydrates, best in form of the green vegetables, including sugar of milk, afford the best composition to save the liver parenchyma, the food being prepared so as not to irritate the gastrointestinal tract.

If the pancreas is seriously involved it becomes a difficult problem to nourish these patients, and milk in some form with additions excluded as one or the other digestive functions of fat, starch or albuminous food fails. The administration of pancreon or similar preparation is useful as a substitute for the lacking secretion.

In prescribing a diet in this as in my other diseases it is of greatest importance to consider the present state of nutrition of the patient (glandular activity), his assimilating power, his age, his occupation, the climate, and the season. These are points rarely taken into proper consideration. It is usually the nutritive value that is considered most, often to the exclusion of all others. Hydrotherapeutic measures are always of great value in the treatment of this disease to influence the circulation, to stop pain, and to subdue inflammation. The hot, full bath, the sitz bath, scotch douches over the liver, the Priesnitz bandage, hot or cold rectal injections to encourage the flow of bile, the Murphy drip, and the ingestion of hot or warm liquids. A combination of the physiological methods with drug treatment is indicated in every case in which the disease is well established. It was formerly thought that certain drugs dissolved stones, but this view has been entirely abandoned; nothing but a pure, free-flowing bile will accomplish this. Durand's remedy, a combination of turpentine and ether, is not given any more as it is disagreeable to take, and we possess antispasmodics and cholagogues far superior to this formerly highly prized remedy.

Olive oil has become quite a popular remedy in this country as well as in Europe. It is given during the acute attacks as well as in chronic cases. A wineglass full of the warm oil morning and night, or only before breakfast, or when an acid gastritis complicates the disease, one or two tablespoonfuls three times daily before eating. It protects the

injured mucous membrane, acts as an antispasmodic and a laxative by keeping the stools soft. The taste may be disguised by adding a few drops of peppermint and by chewing a few tablets after ingestion. The oil of sweet almond or the mineral oils may be used instead. I have had good results in some cases from its use. My patients rarely object to the oil treatment.

Calomel is another remedy freely used in affections of the liver and gall-bladder. Its purgative action is due to an irritation of the intestinal mucous membrane, increasing secretion and peristalsis. Though, according to Stadelman and Pfaff, it does not increase the formation of bile, a larger quantity of the latter is found in the dejections after calomel has been administered. This is thought to be due to a reflex action upon the muscular walls of the gall-bladder and bile-ducts, as well as to a pulling and tearing on these structures, resulting in an emptying of the gall-bladder. I have often observed that liver and gall-bladder shrink considerably in size after its use, a dilated heart becomes smaller, the pulse firmer and fuller, and high tension is lowered. This influence upon the circulation is of great importance when the object is to produce a pure liquid bile.

A number of remedies are used to increase biliary secretion, and of these at present the bile salts are in great favor. It has been proved on animals and men that they increase the fluidity and quantity of bile. Sodium salicylate has been long known as an efficient cholagogue, and the modern preparations like aspirin, diplosal, etc., have the same effect; they are better borne by the stomach and cause less disagreeable systemic symptoms. This is due to the slower liberation of the acid. Podophyllin acts as a cathartic and relieves conjestion and torpidity of the liver. Sanguinarine increases the flow of bile and the digestive glands in general. Juglandin, baptisin, hydrastin, and various other drugs are all freely used for the same purpose with advantage. Ammonium chloride stimulates the secretion of all the mucous membranes of the body and is an excellent remedy in torpor of the liver and chronic hepatitis. Physicians practising in the tropics claim that it prevents abscess of the liver. It must be given in large doses to be effective.

Chologen is a combination of various drugs, among them calomel and podophyllin in minute quantities. I have used it for a number of years with excellent results in gallstone and liver disease. It has to be given from six to eight weeks.

The treatment of gallstone and liver disease with the minieral waters has stood the test of centuries, and an army of sufferers travel annually to the famous springs of Europe and of this country for relief. The numberless cures reported from these watering places testify to the efficiency of the waters and leave no room for doubt. There can be no question, however, that the change from a sedentary indoor life, with the worry and care attached to the daily occupation, to a life in the open, free of care and worry, full of hope to regain health, with regular hours and a suitable diet prescribed by a skilled physician, have much to do with these cures. Nevertheless, the waters have therapeutic properties. They represent an alkaline solution which, given warm or hot one hour before each meal, bathes the mucous membrane of stomach and intestines, frees it from mucus, stimulates peristalsis, and subdues inflammation. During their passage through the gastrointestinal tract some of the mineral water is absorbed and increases the fluidity, quantity and alkalinity of bile. It seems to be rational that a blood richer in water and alkalies produces such changes, though experiments have not shown a direct influence upon bile formation.

The discovery that many of the mineral springs are radioactive, and that this is due to emanations of radium, adds a new factor to explain the efficiency of these waters in disease.

When symptoms of a disease make their appearance every organ of the body is more or less affected, and it is irrational to try to cure the patient by treating one organ only. All organs make blood or distribute it, that is, they add to or subtract something from the blood to make it perfect, so that each cell of the body finds its proper food. When one fails, all fail. In order to function well each organ must get a sufficient supply of pure blood, and this is possible only when blood distribution is perfect. *Blood purity depends on blood distribution.* The gastrointestinal tract is outside of the body proper, and its cleanliness has to be looked after as much as or even more than that of the skin.

The treatment of gallstone disease does not differ in this respect from the treatment of any other disease. To treat gallstone disease we have to influence the general circulation, and especially the abdominal circulation, to cure inflammation and to produce a free-flowing alkaline bile, to expel stones, make them quiescent, or dissolve them with all therapeutic measures and means at our disposal. Not with one drug or with one method.

Medical treatment restores the patient to normal or as nearly so as that can be done. Surgery removes diseased tissue, and must be preceded, combined and followed by medical treatment to be of the greatest and permanent benefit to the patient.

1628 Upperline Street.

HOUSE INFECTION, A POTENT SOURCE OF TUBERCULOSIS.*

By ISAAC W. BREWER, M.D.,

Geneva, N. Y.

Sanitary Supervisor, New York State Department of Health.

For eleven years this association has been studying tuberculosis with a view of obtaining knowledge that may be applied to the prevention of the disease. Year by year our work has been enlarged until to-day when we are for the first time devoting especial attention to housing in relation to tuberculosis.

Tuberculosis is the most universal of all diseases, and there are but few adults who have not at some time or other been infected. Whether or not the disease develops depends upon the virulence of the germs, the mass of the infection, the duration of exposure, and the resistance of the body. The resistance of the body depends upon the food it receives, the work it performs, and the environment in which it lives.

To be successful in a campaign against disease we must first know its cause and then the conditions which make the cause operative. The direct or exciting cause of tuberculosis is the tubercle bacillus. The indirect or predisposing causes are lack of proper nourishment, overwork, excesses, and

*Read before the Sociological Section of the National Association for the Study and Prevention of Tuberculosis, at Seattle, June 16, 1915.

bad housing. It is my province to-day to bring to you some thoughts upon the relation of housing to tuberculosis. In doing so I would remind you that to resolve the problem of the prevention of tuberculosis into its component factors, and to assign to each its proper weight, is at present impossible. The factors which cause tuberculosis to be a problem have gradually developed along with our civilizatlon.

There is a growing opinion among those who are taking an active part in the campaign against tuberculosis that housing is one of the most important factors in the cause of the disease. Dr. E. A. Sweet[1] has recently made a study of tuberculosis among the Mexicans in El Paso, Tex. He found the death rate from that disease among those people to be 554 per hundred thousand, while for the registration area of the United States it is but 149. After discussing various theories to account for this frightful rate, he concludes as follows: "In looking further into the etiology of tuberculosis in the peon class one is struck by the frightful housing conditions which prevail, and these are sufficient in themselves to fully explain the high death rate recorded. When one witnesses the inadequacy of the quarters provided, and the overcrowding and the unhygienic lives these people are forced to lead, it is not necessary to look further for the cause of their trouble, and the entire problem is an open book."

Housing enters into the tuberculosis problem in three ways: (1) The house itself may be infected, that is the germs of the disease may be in the walls, the floors, or furnishings. (2) The house may contain a careless consumptive who may directly infect the other members of the household. (3) The general sanitary condition of the house may be such as to lower the resistance of those who reside therein.

The records of our dispensaries and sanatoria show many instances of what appear to be house infections.

In bulletin No. 27 of the Pennsylvania Department of Health, we are told of a house in Cumberland County which during the period of 1880 to 1905 was occupied by four families, aggregating thirty-two persons. At the time the report was made eleven had developed tuberculosis and there were three suspects.

In England and Scotland much attention has been paid to housing, and at the 1914 meeting of the British National Association for the Prevention of Consumption a considerable part of the program was devoted to the consideration of tuberculosis and housing. At that meeting Sir Robert Philip of Edinburgh said[2]: "Time after time it has been found that tuberculosis has appeared in different families occupying successively the same dwelling. I have before me notes of four such dwellings. In each of these, two or three families came into occupancy one after another, and in each family in course sent tuberculosis patients to the dispensary. In the majority of cases the patient fixed the beginning of his illness at a date corresponding more or less definitely to the date of entrance into the house. After ample allowance for various fallacies, the evidence seems irresistible that the house is frequently the source of infection." He further cites a house from which no less than eighteen cases of tuberculosis came.

The veterinary surgeons tell us the same story regarding stables which have housed tubercular cattle.

The question naturally arises are these cases of house infection, or are they simply incidences of the direct transferrence of the disease. It is well known that tubercle bacilli if enveloped in mucus may remain virulent in the dust of a house for a long time, provided they are not exposed to the direct rays of the sun. Bruckner[3] found tubercle bacilli in an active state in the dust of a room a year after the death of its occupant from the disease.

Hance[4] made some very extensive observations at the Adirondack Cottage Sanatorium, and was able to infect guinea-pigs from the dust of a room where a careless patient had lived.

Winslow and Kligler made a quantitative study of the bacteria in city dust and with special reference to intestinal and buccal forms, and found tubercle bacilli in from 5 to 10 per cent. of the samples of dust taken. (Am. Pub. Health Journal, Sept., 1912.)

Most tuberculous persons who are treated in their homes are far from careful, and spitting on the floor or into the stove is not uncommon. In such homes the children spend most of their time on the floor, and we should not wonder at their contracting tuberculosis.

Those of you who have done any visiting among the poor consumptives well know that, with but few exceptions, every consumptive who remains in the home is a danger to the other members of the household. We all know of exceptions to this statement, but we know of more sad cases of unnecessary infections. My experience with patients in a sanatorium where they had the most careful supervision and where I took great pains to instruct them personally and collectively in personal hygiene, is that it is most difficult to teach them to observe the precautions necessary to prevent the spread of the disease. It is easy to overcome the spitting habit, but to learn the use of the handkerchief is very difficult. I have noticed this in other sanatoria and once was associated with a nurse, "an arrested case," from a well-known sanatorium, who had to be reminded constantly about the use of her handkerchief.

In the home the instruction and oversight is very limited, and it is doubtful if many of the persons treated under these conditions use the handkerchiefs at all. I believe that the home hospital is a dangerous way to handle the consumptive.

Great as is the influence of the consumptive in the home and of the infected house, I believe that housing affects the incidence of tuberculosis mostly by lowering the resistance of those who reside in the slums. As a rule we associate the word slum with the large cities, but if you will look closer you will find that they exist in the small towns and villages, and not infrequently in the rural districts.

Dr. A. K. Chalmers[5] of Glasgow gives the following table for that city:

No. of Rooms	From Phthisis, Death Rate per 1000
1	2.5
2	1.8
3	1.2
4	0.7

The rate for the entire city was 1.8. It will be seen that death rate falls as the size of the house increases.

Several years ago while stationed at one of the forts in Arizona I became interested in the incidence of tuberculosis among the Indians of that

region. Naturally one would hardly expect to find the disease very prevalent among the natives of a climate that is lauded as a cure for the disease. I entered into the problem after reading the reports of Army surgeons who had been stationed in the Southwest during the early days of the American occupation. Most of them reported that the disease was practically unknown among the Indians. However, upon corresponding with the physicians on the several reservations, I was much surprised to learn that the disease was very prevalent among them.

Dr. John R. Walker,[6] long a resident among the Sioux Indians, says that they suffered but little from tuberculosis as long as they lived in tepees, but that the disease began to increase as soon as they built permanent houses. The same has been observed among the Apache tribe, the difference being that in the tepee there was an abundance of fresh air, while in the average Indian home there is nothing but dirt and a polluted atmosphere.

Recently we have had some very illuminating studies upon the effect of confined air upon the human body. As a result of this work we are told that it is cool air in motion that does the good in the open-air treatment of tuberculosis. Without denying the reliability of the work done by the investigators in this country and Europe, I want to say that it seems to me the question has not yet been studied satisfactorily. What we have in a slum is a prolonged exposure to a vitiated atmosphere, and we want exact experiments to show the effect of such an exposure upon the cells of the body. The work of Dr. Crile and his associates has shown that the cells of the body are markedly affected by outside stimuli, and that under certain conditions the cells are badly damaged by such stimuli. We want a study of the cells with relation to the condition of the air in the dwelling.

Those of you who are really interested in the campaign against tuberculosis will do well to investigate the housing conditions in the town of your residence. I think you will find that they are not satisfactory, and that there is no law by which you can prevent them from becoming worse.

THE HARDENING OF CONSUMPTIVES.

BY H. BOYD MASTEN, M.D.,

CIMARRON, N. M.

"GET out and rough it." I suppose that this advice has been given to the majority of consumptives that have been sent to the West and I am quite sure that this bit of advice has caused the death of more consumptives than any other combination of words in the English language. Yet the idea that the doctors have had in mind when giving this advice, was that the patients were to live largely out-of-doors, and by accustoming themselves to heat and cold, storm and sun so to harden their systems that they would become immune to the changing elements and thus avoid taking cold. So after all the advice was not altogether wrong. Where the trouble lay was this: Not one patient in a thousand is competent to follow out this advice in a manner suited to his particular case, for if there is any one disease in which each case is a law unto itself, it is consumption, and the doctors have not made it their business after sending patients west to see that they roughed it in the right way.

Now to start with I want to state a few facts, which from long experience I know to be facts, although I also know that they will be disputed by many of my readers.

First.—Consumptives do far better in the high altitude, dry air, and maximum of sunshine of the Rocky Mountain region than in any other part of the United States.

Second.—The treatment of the fever of a tuberculous patient differs in no respect from the treatment of the fever of other diseases.

Third.—"Getting out and roughing it," *i.e.* hardening the constitution until the patient is immune to colds, with all the accompanying train of evils, even though exposed to rain, hail, snow, and high cold winds, is the best treatment that we have for consumption at the present time.

Now it is the manner of carrying out this hardening process that I want to speak of principally.

In regard to my first proposition: I have seen it proved by statistics that more patients could be cured in the East than in the West, but I doubt very much if there is a doctor in the whole United States who has treated any considerable number of consumptives in the humid regions and an equal number in the Rocky Mountain region, who will not agree with me.

As to the second: I believe that all consumptive patients who run a fever should be kept in bed until their temperature has dropped to normal and remained there for several days, and that then the patients are to be gotten out of bed with as much care as would be used with a typhoid fever patient, for one of our main objects of treatment is to avoid fever. There is one thing that may keep them in bed even after the fever is gone, and that is a weak heart. If the sphygmomanometer shows the pulse pressure to be below 25 mm. of mercury then the patient should be kept in bed still longer and an effort made to strengthen the heart before the patient is allowed to get up.

It has been my experience that practically all patients coming from the East have fever. Either the long train ride or the change to the high altitude brings it on. So all patients coming to the West should be put to bed. The incipient cases will not have to remain there very long, a few days' rest may be all that they will need, but the more advanced cases will be there for a long time and will need constant care and attention. But the hardening process must begin even though they are in bed, so we will get the bed out into the open either in a tent or some sort of a tent cottage. Next, daily baths are to be commenced and are to be given at that time of day that the fever is found to be highest. By using a rubber sheet they can be given with very little inconvenience and without wetting the bedclothes, if the nurse is experienced. These baths must be so given that they will be a pleasure to the patient and not looked upon with dread, for in such case they will do more harm than good. It may be necessary to commence with almost tepid water and to give simply a cold rub, but each day it will be found that the water can be used a little cooler and more plentifully. To begin with, it may be found necessary to surround

the patient with hot water bottles before, and perhaps after, the bath, but in neither case should the bottles be left there long enough to cause the patient to perspire.

After the patient has become accustomed to his daily bath it is time to begin using massage, providing the fever is not running very high, and the massage should follow the daily bath. At first it must be given very gently and for only a few minutes at a time, but gradually it can be given with more force and Swedish movements and vibrations added. As the patient improves he can be taken each day on a wheel stretcher to the bath room for his bath and massage treatment and these can be given on the stretcher or on a table, but as long as the patient has fever he must not be allowed on his feet.

After the patient is up the cold bath can be given each morning to save needless dressing and undressing, and the patient should be taught that the cold douche or bath must be kept up for the remainder of his life. It is well with most, perhaps with all patients, to give them a few moments in a hot-air cabinet before giving them their douche, but care must be taken to see that they do not remain there long enough to cause them to perspire.

Much can be done in the way of hardening the patient by these cold douches but the doctor in charge must be an expert in hydrotherapy and must give individual attention to each patient if the best results are to be accomplished.

Most consumptives, if left to follow their own inclinations, will load themselves down with clothing Heavy wool underclothes, chest pads, leather vests, and all that sort of thing, keep the skin constantly moist and in a most unhealthy condition, ready to take cold at the slightest exposure. All this must be corrected and the patients taught to get along with the least clothing possible; even while confined to bed they should be urged to accustom themselves gradually to a small amount of covers. It will be found often during the heat of the day that they can throw off all covers and lie with their naked bodies exposed to the air, and this they should be encouraged to do. In the *New York Medical Journal* for November 19, 1904, I had an article on "Ideal Tent Life for Consumptives," in which I said, quoting Knopf: "Of the value of carefully conducted solar therapy, I cannot speak too highly. The exposure of the whole body in its nude state to the air and rays of the sun at the same time has a remarkably favorable influence on metabolism, oxygenation, and the general condition of the phthisical patient, aside from the fact that thereby his cutaneous system will be educated to a greatly diminished susceptibility, and intercurrent colds will be much rarer."

I believed at the time I wrote that article that the good results of this treatment came almost entirely from the exposure to the rays of the sun, but now I think that the greatest good comes from the hardening of the patient due to the exposure of his skin to the air. Now if this really is the case then the only logical course of procedure is to expose the skin of our patients to the air as much of the time as possible, and we can best do this by adopting for them the costume of the aboriginal inhabitants of this region: a breech-clout and a pair of moccasins with a blanket for chilly days.

In the North and East this "Indian garb" would hardly be feasible but in the Southwest it is perfectly practicable, if one has a suitably located sanatorium and providing only one sex is admitted. In many sanatoriums, both East and West, it has been the custom to give the patients sun baths, but usually for only a short time each day, or at less frequent intervals. By using the "Indian garb," after the patients have once attained a good coat of tan, they are able to take almost a continuous sun bath throughout the day, and there is not the least doubt but that it is very beneficial.

Great care must be used in accustoming the patients to the direct rays of the sun while they are acquiring their coat of tan. I have seen reactions brought on fever-free patients by what seemed a very slight exposure, also I have seen them blistered. Either expose them for only a few minutes at a time or expose only a leg or forearm at first. It is best to have the patient thoroughly accustomed to the "Indian garb" before venturing into the sun at all.

At first the head must be protected from the direct rays of the sun but after the patient has grown a football head of hair this is not necessary.

If the above treatment is carefully followed, very little medicine will be needed. Perhaps a tonic or a laxative may be of service at times. In some cases tuberculin will do much good, but unless a doctor has had years of experience with tuberculin he should never use it in his private practice for it is a dangerous remedy in inexperienced hands.

One treatment that is of the greatest value is compression. It should be used in every case where a cavity exists, and where the other lung is in reasonably good condition. It should be used also where there is an extensive involvement of one lung and it should be used early, not as a last resort. It will usually lower the fever and reduce the cough and the quantity of expectoration.

A good mixed diet should be given, but the days of stuffing the patients are over. There is no advantage in keeping the stomach and bowels constantly overloaded as it leads to indigestion, diarrhea, and other ailments. Patients can assimilate only so much and if they are constantly stuffed they get a distaste for food. If they are averse to eating fat meat and other forms of fat at the table, it is best to give them the fat in the form of cod liver oil.

While the patients have fever they must be kept on liquid diet: Milk to which lime water should be added, soup, fruit juice, egg nogs, thin boiled custards, and gruels will be all that is needed. When the fever has diminished the diet may be increased, but the patient should not be put on regular diet until the fever is gone.

With this treatment, if followed in the manner I have indicated, the problem of exercise is not such a difficult one. If we keep the patient in bed until the fever is gone and substitute massage and the Swedish movements for the exercise that is ordinarily given, it will be found that when the patient is allowed to get up the heart will be in good condition and the patient will be able to exercise to a considerable extent without danger to this most vital organ. Treated as patients usually are, it takes a doctor with the wisdom of Solomon to regulate properly the amount of exercise that they should take.

The Incubation Period of Syphilis.—Georges Thibièrge finds that this varies between 14 and 42 days, although exceptional instances of from 50 to 90 days have been observed. These wide limits introduce an element of perplexity into the medico-legal aspects of the problem. —*Annales de Dermatologie et de Syphiligraphie.*

THE VALUE OF THE WASSERMANN REACTION.

IF one follows medical literature at all carefully one inevitably acquires the impression that, as a general rule, a positive Wassermann reaction is considered to be pathognomonic of syphilis. Conversation with these authors will reveal the fact that they all appreciate that it is not a specific reaction and that, when the result of the test is in conflict with the clinical and historical evidence, they insist upon its repetition or even disregard it altogether. Nevertheless, it is apparent that in the minds of most clinicians a four plus Wassermann and a diagnosis of syphilis are very closely associated. It is probable that the less extensive is the man's experience the closer is this association. This condition of affairs is perhaps the natural result of several influences. In the first place, the Wassermann reaction is positive at one time or another in a great majority of the cases of syphilis. This establishes it as a fairly constant symptom toward which one naturally looks in the solution of any diagnostic problem. Secondly, the history is notoriously unreliable in practically all cases of venereal infection. Patients are prone to conceal the knowledge of an initial lesion, they may have honestly forgotten it, or they may never have been conscious of it. In addition there are, no doubt, many instances of extragenital infection in which an initial lesion is never seen and the onset of the disease never apparent. Thirdly, when the reaction was first proposed it was believed to be specific in its nature and in all the publicity which has been accorded to it, its non-specificity has not been sufficiently emphasized. Its apparently close relation to other complement-fixation tests which are specific has aided in this confusion.

Sooner or later, however, a man will run into a case in which the only evidence pointing to a diagnosis of syphilis is a strongly positive Wassermann. The history may be assuredly negative, as in the case of the serologist who found a positive reaction in his own blood. All the evidence obtainable points to the fact that the patient is free from lues, except this one test. What answer shall be made? It has been recognized that there are several conditions in which a positive Wassermann may be obtained. Leprosy, scarlet fever, malaria, lead poisoning, pulmonary tuberculosis, and the acidosis of diabetes have been described as being among them. But it is not very improbable that there are other conditions of which we at present know nothing, which may produce these complement-binding substances in the blood serum. Furthermore, it has been found that sometimes the result of the test changes from time to time or is different when done in different laboratories.

The question of technique is a vexed one. Almost all of the serologists at present have varied more or less from the original Wassermann technique, and it is necessary to consider the influence of these variations upon the results obtained. In an attempt to clear up some of these vexed points Uhle and MacKinney (*Jour. Am. Med. Assn.*, 1915, lxv, 863) submitted 325 specimens of blood collected from 292 individuals to seven serologists and compared the results returned with the clinical pictures of the patients and with each other. Some of these serologists used more than one antigen, so that there were ten sets of reports returned. From the normal and non-syphilitic cases the positive results varied from 2.6 to 18.1 per cent. There were conflicting reports, but what is worse, "conflicting reports from the same serologist on specimens from the same individual withdrawn at the same time under identical conditions." All of the laboratories agreed in 21 per cent. of the specimens, they disagreed materially in 19 per cent., and varied in from one to four of the ten results in 60 per cent. In other words, if a specimen of blood from the same individual be submitted to ten tests by different serologists, there is one chance in five that the tests will agree. This confusion is especially well illustrated in the case of one patient who flatly denied any possibility of luetic infection or having received any antileutic treatment. His blood was examined four times. On the first examination there were four positive and no negative reports; twelve days later three positives and two negatives; the following day five positives and one negative, and six weeks from the first examination two positives and four negatives. One laboratory yielded all positive reports; a second, one positive and three negatives; the third, two positives and one negative, and the fourth, first positive, then negative, again positive, and finally a negative. Since these tests were all done by competent serologists the results are most disquieting. One is tempted to say that the reaction besides being illogical in principle is worthless in its application. And yet the systematic use of this test has given results of inestimable value. It was with its help that paresis was definitely established as syphilitic in nature before the organisms were found in the brain. In numberless instances the reaction has helped to determine the diagnosis and lead to a curative treatment. In addition the clinicians tell us that only by its use can the treatment of the disease be satisfactorily guided.

What then can be said of the value of the Wassermann reaction as a diagnostic procedure? A single negative result certainly does not exclude syphilis, and even a series of them may be overruled in the presence of sufficient clinical evidence. We may, therefore, conclude that a negative result has little or no value except as it may confirm the clinical

diagnosis. A positive test is a frequent symptom of syphilis; and therein lies its chief danger, for the most serious mistake that can be made is to pronounce a man syphilitic and thereby condemn him to a lengthy treatment and lifelong suspicion without adequate reason therefor. But the Wassermann is not pathognomonic of syphilis since it occurs in other conditions, and it cannot be too strongly emphasized that *a diagnosis of syphilis must not be made upon the Wassermann reaction alone.* In the future, as in the past, the chief reliance must be placed upon accurate and complete clinical observation. It seems highly probable that the Wassermann will some time be completely supplanted by a true specific reaction which will be founded upon a rational basis. Until that time the Wassermann will be extensively used, and rightly so, provided that it be not too blindly followed.

THE VISCOSITY OF THE BLOOD.

FUTURE studies of arterial pressure will probably be considered in connection with the viscosity of the blood which phenomenon has an intimate bearing upon the tension of the vital fluid. Alfred Martinet has written an important monograph on this theme, entitled "Pression Arterielle et Viscosité Sanguine," which is reviewed at length in the *Journal de Médecine et de Chirurgie,* July 25, 1915. It is pointed out that the fathers of medicine paid particular attention to the degree of viscosity of the blood while performing venesection, just as they were punctilious in noting the various qualities of the pulse. To-day the scientific measurement of blood pressure finds its counterpart in the invention of an instrument for the accurate estimation of the viscosity of the blood. The viscosimeter consists of a U-shaped capillary tube, one arm of which is immersed in distilled water and the other in the specimen of blood to be examined. The relation between the height of the liquid in the first tube and the height of the liquid in the second represents the degree of viscosity of the blood. Normally this ratio varies between 3.8 and 4.5, which may be regarded as a physiological constant in the same sense as the temperature, pulse, and blood pressure. Under pathological conditions the extreme figures are 1.9 and 7.8. The degree of viscosity of the blood is of diagnostic importance only when considered in connection with other signs or symptoms.

In hydremia, such as that present in nephritis and in certain types of anemia, the viscosity of the blood is low. The lowest figures for this viscosity are observed in the cardiac and nephritic edemas. In anoxemia the increased content of the blood in carbon dioxide raises the viscosity. Venous blood is more viscous than arterial, and the blood of cyanotic or asphyxiated patients has a high degree of viscosity. This is also present in the hyperglobulia of plethora and in the hyperleucocytosis of leucemia. In the diabetic and the gouty the viscocity of the blood is increased.

The above facts are only of secondary interest. The viscosity of the blood is of real diagnostic significance only when considered in association with the blood pressure—a study connoted by the term "sphygmoviscosimetry." This has been applied by Martinet in 157 patients, who are divided into three categories from this viewpoint. The first of these groups comprises the so-called "eusystolics" in whom the arterial tension is somewhat proportionate to the viscosity of the blood. If the tension rises the viscosity rises also, so that the ratio between the two is always represented by the figure 4. None of the patients in this group suffers from circulatory or renal disorders. The second category comprises the so-called "hypersystolics" or the "hypertensive-hypoviscous" individual, in whom the blood pressure is considerably elevated both absolutely and relatively to the viscosity which is feeble. The ratio is 4.5 or more. In the patients belonging to this group there is some disorder of the cardiovascular and renal systems. To the third category belong the "hypotensive-hyperviscous" individuals, in whom the blood pressure is feeble in relation to the viscosity which is increased, the ratio being 3.7 or less. The patients in this group show an increased venous engorgement such as that accompanying initial disease or chronic disease of the lungs.

What are the practical applications of the above facts? In the first place they enable one to differentiate the hypertension caused by arteriosclerosis from that which is not caused by the latter. Cases of hypertension in which there is an increased viscosity are generally instances of simple plethora, of gout, or of diabetes, in all of which the cardiorenal and vascular apparatus is not organically impaired. Hypertension with a low viscosity indicates cardiorenal disease with a more or less pronounced degree of arteriosclerosis. The former group of cases may be said to belong to the presclerotic stage; the disorder is purely functional and may be completely cured. One of the earliest signs of the onset of sclerotic changes is the diminishing viscosity of the blood.

In the second place, the practice of viscosimetry enables one to determine the precise indications for the administration of the iodides. These should not be given in all cases of hypertension. As Huchard has shown, they should be reserved for a strictly limited group. Potassium iodide tends to diminish the viscosity of the blood, and for this reason it is contraindicated in cases of pronounced hypertension with low viscosity in which a further diminution of viscosity would increase the albuminuria and the hemorrhagic manifestations. The iodides are useful in the following two groups of cases: (1) In plethoric, gouty, and diabetic patients, in whom an increased arterial tension is associated with an increased viscosity of the blood. In these cases in which there is no evidence of weakness in the hypertrophied heart or of renal insufficiency, the administration of the iodides in conjunction with an appropriate diet enables one to diminish both the hypertension and the hyperviscosity. (2) In cases of venous stasis, with a normal or diminished arterial tension and with a viscosity increased by virtue of the excess of carbonic acid in the blood, the iodides correctly administered in association with a cardiac tonic tend to stimulate the heart, improve the circulation, and diminish the carbon dioxide

content and viscosity of the blood. In these cases the increase in the tension of the blood is accompanied by an improvement in the circulation and in the general condition of the patient.

THE SUPERINTENDENCY OF THE RANDALL'S ISLAND HOSPITAL.

PHYSICIANS no less than the general public will keenly regret that provision for the feebleminded in the new constitution, now about ready to be submitted to the people, does not create an entirely separate State commission for the feebleminded as set forth in these columns on May 1 of this year. However, we presume that, as in many another of the new constitutional provisions, State-wide compromises had to be made. We must still labor for a more general recognition of the needs of a special State Commission for the care and treatment of the feebleminded. In the meantime the citizens of New York should see that no steps backward are taken in our own city regarding the care and treatment of the feebleminded. The splendid work which Mayor Mitchel and Commissioner Kingsbury have done in planning the reorganization of Randall's Island cannot be too highly commended. The Commissioner of Charities has had the excellent cooperation of a special advisory commission of lay and professional experts to assist him to lay out his constructive program. We regret to learn, however, that the Commissioner has not been guided by one of the very foundation principles laid down by his committee. The committee specifically indicated that the new superintendent should be a physician well trained in the special work of neurology and psychiatry as well as one experienced as an executive officer in the special field of institutional work. Any one familiar with the new educational and industrial training of the feebleminded knows that there can be no half-way measure, no lay control of such an intricate medical and psychological problem as this work entails.

The Civil Service qualifications already published call for no written or oral part of the examination to be based upon the neurological or psychiatric aspect of this great problem. Any lay individual may be an applicant for the position who has had "two years' experience in an executive capacity in an institution for the sick insane or mentally defective tending to qualify him for the position sought." What does an "executive capacity" mean? If it means that such an aspirant for the position must have served as a medical officer, why should it not have been so stated instead of leaving the matter in doubt so that even a trained nurse or a hospital steward can qualify? Again: does the term "sick insane" mean to state that all the insane are not sick? Finally, the compensation for the successful applicant is to be but $3,500 a year, a thousand dollars less than that for the superintendency at the Letchworth Village for mental defectives, a by no means more onerous position to fill. Furthermore, this salary is the minimum for any superintendency in the State Hospitals for the insane of this State. If there has been no intent on the part of the Commissioner to place an untrained neurologist and psychiatrist in this most important position in the thorough reorganization of the Randall's Island institutions, why did the Civil Service Commission not take the requirements of superintendency at the Letchworth Village as a pattern? The above ambiguous requirements for the superintendency of the Randall's Island institutions would then have read: "The applicant must be a physician in good and regular standing, thirty years of age, with five years' practical experience in the care and treatment of the feebleminded; the written examination to cover medical qualifications including his *conception of the proper development of an institution for the feebleminded*, and his *knowledge of feeblemindedness*."

It cannot be that the Commissioner of Charities was unaware that even the severe requirements laid down for the position of superintendent of Letchworth Village could be easily met by at least a score or more physicians within the confines of New York State, or even the city itself.

Finally, it does not seem possible that Mayor Mitchel and Commissioner Kingsbury are unaware that the greater part of their efforts toward a radical reform and upbuilding of the Randall's Island institutions is seriously jeopardized at this most important first step of selecting a properly qualified and efficient executive officer to take up the great task of providing the proper care and treatment of the feebleminded on Randall's Island, an object which the medical profession and the general public have been long waiting for, and which it lies in their hands now to make or mar.

A PERIL OF THE "PICTURES."

THOSE whose practice brings them a good deal among children may have observed during the past few years a notable increase in the number of cases of pavor nocturnus. In a large percentage of these instances the information has probably been volunteered by the parent or guardian that the child had been to the "moving picture show" during the preceding afternoon or evening. In other instances this information has been elicited on questioning by the physician. Of course, the popularity of motion pictures and the so to say normal frequency of night terrors in children would seem to indicate the possibilities of a mere coincidence in such cases; nevertheless the association between the two phenomena—on the one hand, a phantasmagoria with which the adventures of "Deadwood Dick" are tame in comparison, and on the other hand, a terrifying dream in which are represented one or more of the incidents of the pictorial play, is very often palpably one of cause and effect. It may be alleged that the nocturnal attack is primarily the result of an unstable nervous organization. But all children have an unstable nervous organization. Then one may be reminded of the causative rôle of hypertrophied tonsils, adenoid growths, dietetic errors, etc. It must be admitted that these are all well-recognized causes of night terrors. But these do not exonerate the contributory culpability of the abnormal and excessive stimulation of the child's

delicate nervous system by the scene of adventure thrown upon the canvas.

Less than a generation ago the occasional "Punch and Judy" show and the annual visit of the circus were the limit of entertainment with which the infantile mind was regaled. Nowadays it is feasted upon the antics of the clown, the thrills of the Wild West, the delirium of war, the seduction of the love drama, and the hair-raising exploits of the jungle. All these follow one another in kaleidoscopic succession and little wonder if the effect upon the immature mind is more than one of mere bewilderment.

Physicians cannot afford to ignore the numerous hygienic aspects of motion pictures which have become an important institution of modern life. Most of these have already been freely discussed and have been provided for more or less adequately by regulations as to ventilation, lighting, the prevention of eyestrain, etc. The moral and the educational features of motion pictures constitute separate chapters. Their relation to mental hygiene in the case of the growing child is one that demands the close attention of the medical profession.

SEPTICEMIA IN INFANCY.

AN interesting exposition of this subject is contributed by Hutinel to the *Progrès Médical*, August, 1915. He notes that septicemia is relatively uncommon during adult life, occurring usually in association with the puerperium, severe microbic infections, pronounced cachexias, and sometimes from a contaminated wound. The adult is, as a rule, well protected by his phagocytes and blood plasma. Septicemia is relatively more common during infancy than during adult life for the following reasons: In the infant the alkalinity of the blood is less than in the adult, and in the former there is a certain degree of glycemia. These circumstances may account for the fact that the blood of young animals is a better culture medium for bacteria than the blood of older animals. The young infant has 43 per cent. of polynuclear leucocytes corresponding to the 64 per cent. possessed by adults; the phagocytic property of the blood is therefore less in infants than in adults. In addition the former have a smaller amount of alexins or complement than the latter.

During the course of one year Hutinel has had the opportunity of studying at autopsy the bodies of nineteen premature infants. Of these fifteen showed signs of septicemia, the colon bacillus being the most frequent cause, and the streptococcus and staphylococcus coming next in order. The symptoms during life were variable: refusal or inability to nurse, vomiting of food or of bile, diarrhea, hemorrhagic bronchopneumonia, and hemorrhages into the skin and viscera. The most marked sign, however, was the pronounced loss in weight. The temperature assumed a parabolic curve, reaching subnormal just before death. The loss in weight was progressive, excepting when edema was present, and the color of the skin was apricot yellow.

The infant born at term, though less susceptible to septicemia than the premature infant, nevertheless manifests a peculiar liability to this condition. In many instances the infection antedates birth. When fully developed, the symptoms may be, in addition to the loss of weight already mentioned, a brief rise in temperature, a hypothermia (as in colibacillemia), but more frequently a persistent vomiting and diarrhea. The infection may gain access to the body through the skin, lungs, gastrointestinal tract, and genitourinary apparatus. Any of the organs of the body may be involved. Not all of the cases are fatal, the typhoid septicemias particularly being those in which recovery may ensue.

PERFORATING SIGMOID DIVERTICULITIS.

FOR a number of years past attention has been directed to the acquired diverticula of the large intestine, which are found chiefly in the free portion of the sigmoid. In an interesting study of this subject E. Kummer (*Revue Médicale de la Suisse Romande*, August 20, 1915) calls attention to the diversity of statistics as to the frequency of acquired diverticula, Telling reporting twenty-eight instances in 13,800 autopsies, and Graser fifteen in 28 autopsies. Among the many pathological processes that may arise in these diverticula are mentioned pseudo-tumors resembling cancer, inflammatory changes causing intestinal obstruction, circumscribed abscess formation causing sigmoiditis or perisigmoiditis, and perforation of such abscess into neighboring organs with the production of localized or generalized peritonitis. The author refers particularly to a type of perforation *d'emblée* into the peritoneal cavity with a resulting generalized peritonitis. A review of the forty-two cases thus far reported shows that the condition occurs chiefly in males and at an advanced period of life. The cause is an infection of the bowel wall by the colon bacillus and a subsequent necrosis. The widespread character of the peritonitis that immediately arises is explained on the basis of the following facts: (1) the suddenness of the perforation which gives no time for the production of a fibrinous protective barrier; (2) the extensive radius of mobility of the sigmoid, and (3) the intensity of its peristalsis. Favoring circumstances are a preexisting enterocolitis with diarrhea and the use of drastic purgatives. The characteristic though inconstant clinical symptom of diverticular perforation is the "pistol-shot" pain in the left flank occurring in an individual of advanced years during the act of defecation. If the condition is promptly diagnosed and operated upon without delay, a reasonable hope for recovery may be entertained.

CERTAIN UNCLASSIFIED FEVERS.

AN interesting paper on this subject is contributed by Richard Stein to the *American Journal of the Medical Sciences*, August, 1915. He discusses a group of cases which present the general clinical aspect of typhoid fever, but in which the infection is mild, the temperature curve resembling that of the third week of a mild case of typhoid fever. The general prostration, the splenic enlargement, and the form of the temperature curve would seem to indicate that one is dealing with a mild or abortive case of typhoid fever. But blood cultures are negative. So likewise are the agglutination reactions with the typhoid bacillus, the paratyphoid organ-

isms, and other members of the typhoid-colon group. The suggestion is made that these cases represent a mild bacteriemia in which the infective agent is unknown. They may possibly be cases of so-called autointoxication, although there is no increase in the decomposition products in the urine. It has recently been proposed to call the fevers resembling typhoid fever entericoid or paraenteric fevers. One puzzling aspect of these cases is that some of them after a short subsidence merge into severe cases of typhoid fever. The suggestion is made that the initial stages of typhoid fever have not been subjected to the same careful observation and study as the later stages. There is a group of cases which clinically are unmistakably typhoid fever but in which the laboratory confirmation is wanting. Stein believes that typhoid fever, a clinical entity, is produced by a variety of microorganisms, some of which are yet to be isolated.

News of the Week.

Fecundity of Prussian Women.—A Berlin correspondent of *The Sun* writes that according to the census taken in December, 1910, there were at that time in Prussia 7,809,360 married, widowed and divorced women, of whom only 575,519 had no children. Of these 82,921 women had twelve children, 42,629 had thirteen, 27,064 had fourteen, 14,624 had fifteen, and 17,337 sixteen children or more each. As many as 789 women had more than twenty children. Altogether the 7,250,000 Prussian mothers had given birth to 28,312,898 children, or an average of four children each.

American Red Cross Shipments.—On Sept. 11 the steamer *Samland* carried eighty-two cases of hospital supplies consigned to the Red Cross in London, and on the following day the American Red Cross sent sixty cases of hospital supplies on the steamer *Dvinsk* to Russia.

The Needs of the American Red Cross Hospital at Kiev.—A number of Americans resident in Petrograd have sent Captain Hough to this country to urge the claims of the American Red Cross Hospital at Kiev which is in danger of being closed on account of lack of funds. The hospital is said to be one of the most efficient military institutions in all Russia. The head of the surgical staff, Dr. Shiveley of Ohio, has been honored with a general's commission in the Russian service, because of his work. The average number of wounded soldiers that daily come under the care of Dr. Shiveley is more than 700, and among these are some of the most serious cases that are brought from the battle fronts. The hospital is now running on a guarantee subscribed by the American residents of Petrograd, who have raised sufficient funds to keep it in operation until November. Unless sufficient contributions are forthcoming in the interval, the hospital work will have to be discontinued.

Eighty Million Dollars to Belgian War Victims.—The total value of the food and other relief supplies sent into Belgium by the Commission for Relief in Belgium during the past ten months is more than $80,000,000, according to a statement issued from the New York office recently. Up to the first of July there was sent to Belgium for the relief of the noncombatant population of the country 305,737 tons of flour, 15,275 tons of rice, 40,680 tons of corn, 15,546 tons of peas and beans, and other supplies, the total weight of which was 423,583 tons. In addition to the supplies sent to Belgium the commission has since the first of April last been feeding the destitute people of the German-occupied territory of France. These French sufferers number more than 2,500,000. More than 91,000,000 pounds of supplies have been sent to that part of France. Also about 10,000 tons of food have been donated to relief work in the Grand Duchy of Luxemburg, also under German rule.

Reported Sinking of a Belgium Relief Steamer.—A dispatch from Holland last week stated that a Dutch steamer reported the torpedoing of a steamer flying the signals of the Belgian Relief Commission. Ten of the crew of the steamer were rescued by trawlers.

Dr. Joseph A. Blake of this city, who has been in charge of the American Ambulance in Paris since the beginning of the war, has resigned to become surgeon in chief of the new English Hospital at Frisorangis, near Fontainebleau, organized recently by Lady Alan Johnstone, wife of the British Minister at The Hague. Dr. Blake will have full charge of the hospital, which is to supersede that of the Trianon Palace at Versailles as the chief British hospital in France.

Official Praise for the American Ambulance.—A dispatch to *The Sun* states that Section 2 of the American Ambulance, stationed at Pont-a-Mousson and engaged in removing the wounded in the Bois-le-Pretre forest and vicinity, was recently mentioned in the divisional order of the day. The War Cross was awarded to the section and the commanding officer, Edward Salisbury, who received separate mention, was decorated individually. The base hospital occupied by the section is said to be the nearest to the enemy trenches of any in France. The German artillery bombarded the hospital all of one night last August, killing a French orderly and mortally wounding another.

Leprophobia.—A dispatch from Pittsburgh in the *Evening Post* states that a former United States soldier, who contracted leprosy while serving in the Philippines, and who has been under strict guard in a tent at the municipal hospital since his appearance in Pittsburgh several months ago, will be returned to Washington in an automobile. After he has been turned over to the army authorities, the machine will be burned.

New York City Death Rate.—During the week ending September 11 there were 1,355 deaths in this city, giving a rate of 12.17 per thousand, as compared with 1,206 deaths and a rate of 11.27 for the corresponding week of 1914. The rate here given is figured on the population estimated upon the normal increase over the United States census of 1910. The Health Department does not accept the figures of the State census of 1915, but has made another estimate based upon calculations of the registrar, according to which the population of the city is 5,597,000. The rate for the past week, based on this raised estimate, would be 12.63; based upon the official population determined by the State census it would be still greater. The rate for the first thirty-seven weeks of 1915 is 13.54, that for the corresponding period of 1914 was 13.97.

Chicago Death Rate.—The total number of deaths for the week ending September 11 was 1,424, giving a death rate of 30.3 per thousand of population, as compared with 619 deaths and a rate of 13.2 for the preceding week, and 490 deaths and a rate of 10.8 for the corresponding week in 1914.

The large number of deaths and correspondingly high rate is due to the inclusion of 812 deaths in the Eastland tragedy, which were reported during the week after the recovery of the bodies.

Opposed to Twilight Sleep Films.—The commissioner of licenses recently forbade the "Motherhood Education Society" to give public moving picture exhibitions of the twilight sleep technique with Dr. K. E. Schlöningh from Freiburg as the lecturer. His prohibition was strengthened by the opinion of a number of physicians that the pictures were of no educational value. The company has applied for an injunction restraining the commissioner from interfering with the production. At a meeting in Pittsburgh last week of the American Association of Obstetricians and Gynecologists a number of the members expressed themselves as strongly opposed to the routine employment of this method in cases of childbirth.

Insanitary Conditions on Blackwell's Island.—The August Grand Jury has handed up a presentment to Judge Crain in General Sessions in which the statement is made that the housing of prisoners on Blackwell's Island is a disgrace to New York City. A committee of jurors visited the prison and institutions on Blackwell's and Riker's Islands and reported that "the sanitary conditions at Blackwell's Island are substantially the same as they have been for the past sixty-five years, and the buildings there are overcrowded to such an extent as to constitute a real menace to the health of the inmates." Commissioner of Corrections Katharine B. Davis declared that the overcrowding in the prisons is due to lack of funds for the development of Riker's Island, where buildings are now being erected largely by prison labor.

Fifty Patent Medicines Condemned.—The United State Department of Agriculture announces more than half a hundred successful prosecutions under the Sherley amendment to the Food and Drugs Act, which prohibits false and fraudulent claims as to the curative or therapeutic effects of drugs or medicines. Criminal prosecutions against the manufacturers were brought in twenty-five cases, but in thirty-one instances the falsely and fraudulently labeled medicines were seized while in interstate commerce. Claims made by the manufacturers for the curative powers of these preparations ranged from tuberculosis, smallpox and diphtheria to coughs, colds and scalp diseases. A number of other criminal prosecutions and seizures are pending in various Federal courts throughout the United States because of alleged violations of the Sherley amendment similar to those which have already been tried. The officials charged with the enforcement of the Food and Drugs Act are of the opinion that the evils of the patent medicine business can be stopped only by most drastic action of this sort.

An Endorsement of the Health Board Ordinance Regarding Patent Medicines.—The American Public Health Association at its recent meeting in Rochester, N. Y., adopted a resolution opposing the sale of patent medicines and nostrums whose constituents are unknown to the health authorities; heartily endorsing the ordinance of the New York City Department of Health, requiring the manufacturers of proprietary remedies sold without a physician's prescription to file with the department a statement of its active constituents and therapeutic claims, and recommending to other municipalities the adoption of this or similar measures for the proper safeguarding of the public health. The Health Department announces that the new registration ordinance is meeting with encouraging response. A considerable number of manufacturers have already applied for registration, and several of the larger retail druggists in this city have notified the manufacturers of patent medicines that they will refuse to handle after January 1 all patent medicines which fail to comply with the Health Department's new ordinance.

New Hospital for Drug Users.—Commissioner of Corrections Katharine B. Davis has received a check for $18,000 from John D. Rockefeller, Jr., to be applied toward the construction of a new drug hospital on Riker's Island. Mrs. William K. Vanderbilt recently sent Dr. Davis a check for $10,000 to be put to the same use. This means that work on the building, which will accommodate 132 patients, will begin at once. The hospital will be built of hollow tile and stucco in modified Spanish mission style. It will contain four wards, a dining room, kitchen, day room and doctors' quarters. The hospital will be under the charge of Dr. Ernest S. Bishop.

Examination of Candidates for Assistant Surgeon United States Public Health Service.—Boards will be convened at the Bureau of Public Health Service, Washington, and at the marine hospitals of Boston, New York, Chicago, St. Louis, Louisville, New Orleans, and San Francisco on Monday, November 1, 1915, at 10 o'clock A. M. for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health Service. Candidates must be between 23 and 32 years of age, graduates of a reputable medical college, and must furnish testimonials from two responsible persons as to their professional and moral character. Credit will be given in the examination for service in hospitals for the insane or experience in the detection of mental diseases. Candidates must have had one year's hospital experience or two years' professional work. Candidates must be not less than 5 feet 4 inches nor more than 6 feet 2 inches in height, with relatively corresponding weights. After four years' service assistant surgeons are entitled to examination for promotion to the grade of passed assistant surgeon. Passed assistant surgeons after twelve years' service are entitled to examination for promotion to the grade of surgeon. Assistant surgeons receive $2,000, passed assistant surgeons $2,400, surgeons $3,000, senior surgeons $3,500, and assistant surgeon-generals $4,000 a year. When quarters are not provided, commutation at the rate of $30, $40, and $50 a month, according to the grade, is allowed. All grades receive longevity pay, 10 per cent in addition to the regular salary for every five years up to 40 per cent after twenty years' service. The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For invitation to appear before the board of examiners, address "Surgeon-General, Public Health Service, Washington, D. C."

Medical Society Elections.—THE AMERICAN PUBLIC HEALTH ASSOCIATION at its meeting in Rochester, N. Y., elected the following officers: *President*, Dr. John F. Anderson, U.S.P.H.S., director of the Hygienic Laboratory, Washington; *First Vice-President*, Dr. George W. Goler, health officer, Rochester, N. Y.; *Second Vice-President*, Dr. Charles J. Hastings, medical officer of health, Toronto, Ont.; *Third Vice-President*, Dr. Omar Gil-

lette, Colorado Springs, Col.; *Treasurer*, Dr. Lee K. Frankel, Metropolitan Life Insurance Company; *Secretary*, Professor Selskar M. Gunn, Boston; *Honorary Members*, General W. C. Gorgas, surgeon U. S. army, Washington, D. C.; Dr. Stephen Smith, State Board of Charities, New York; Dr. Frederick Montizambert, director general of public health, Dominion of Canada, Ottawa, and Dr. Henry D. Holton, Brattleboro, Vt.

THE NEW MEXICO STATE MEDICAL ASSOCIATION, at its meeting in Las Vegas the second week in September, elected the following officers: *President*, Dr. Evelyn Frisby of Albuquerque; *Vice-Presidents*, Drs. C. S. Lorey of Las Vegas, J. W. Kingsinger of Roswell, and A. H. Delong of Gallup; *Secretary*, Dr. R. E. McBride of Las Cruces; *Treasurer*, Dr. F. E. Tult of Albuquerque. The next annual meeting will be held in Albuquerque.

THE ASSOCIATION OF SURGEONS OF THE CHESAPEAKE & OHIO RAILWAY held its annual meeting at White Sulphur Springs, W. Va., on September 13 and elected the following officers: *President*, Dr. Southgate Leigh, Norfolk; *Vice-Presidents*, Drs. E. H. Griswold, Peru, Ind.; R. S. Griffith, Basic, Va., and A. O. Taylor, Maysville, Ky.; *Secretary-Treasurer*, Dr. L. G. Bentley. The next annual meeting will be held at Old Point Comfort, Va.

Obituary Notes.—Dr. P. VAN BENSCHOTEN FOWLER of Centre Moriches, L. I., died at Brentwood on September 14, following an operation. He was born in Newburgh, N. Y., in 1866 and was graduated from the Medico-Chirurgical College, Philadelphia, in the class of 1897. He was a member and one time secretary of the Suffolk County Medical Society, and a member of the State Society, of the American Medical Association, and of the Associated Physicians of Long Island, and was also on the medical staff of the Babylon Hospital.

Dr. ROBERT GAMALIEL CORNWELL of Riverhead, N. Y., died at his home of cardiac disease on September 16. He was born in Brooklyn in 1852 and was graduated from the Long Island College Hospital in 1875. He was coroner for Suffolk County and had formerly been health officer of Riverhead.

Dr. SUSAN LA FLESCHE PICOTTE of Walthill, Neb., died at her home on September 18 at the age of 49 years. She was a daughter of Pierre La Flesche, or Iron Eye, the last of the great chiefs of the Omaha tribe, and had devoted her life to the interests of her tribe, by whom she was regarded as the leader. She was graduated from the Woman's Medical College of Philadelphia in the class of 1889 and was a member of the Nebraska State Medical Society.

Obituary.

AUSTIN FLINT, M.D., LL.D.

NEW YORK.

DR. AUSTIN FLINT, whose long life of professional activity was brought to an end on September 22 by cerebral hemorrhage, won fame in early life as a physiologist and in later years as an alienist. He was the son of Austin Flint, Sr., one of America's greatest physicians, and was born in Northampton, Mass., on March 28, 1836. On leaving Harvard College he began the study of engineering, but soon abandoned that to prepare for his father's profession. He studied medicine at the University of Louisville in 1854-6, and then went to Philadelphia, securing his degree from the Jefferson Medical College in 1857. He began practice that year in Buffalo, where he was editor of the *Buffalo Medical Journal* and professor of physiology at the University of Buffalo. In 1859 he removed to New York City and was appointed professor of physiology at the New York Medical College. In 1860 he was called to the chair of physiology at the New Orleans School of Medicine but left there in 1861, returning to New York. From 1862 to 1865 he served as acting assistant surgeon in the Union Army, and at the same time filled the chairs of physiology at Bellevue Hospital Medical College, of which institution he was one of the founders, and at the Long Island College Hospital. He resigned the latter in 1868 and left the Bellevue College in 1898 to take the chair of physiology at Cornell University Medical College. From 1874 to 1878 he was surgeon general of the National Guard of the State of New York.

While devoting much of his time to physiological experimentation and teaching, Dr. Flint was also a diligent student and practitioner of psychiatry. He was appointed consulting physician to the Manhattan State Hospital for the Insane in 1896, and was one of the State's alienists at several of the Thaw trials, maintaining to the end that the murderer of Stanford White was a paranoiac. He was the author of a number of books and articles, among which may be mentioned: A treatise on "Physiology" in five volumes, 1866-75; "Physical Effects of Prolonged Muscular Strain," 1871; "Text-book of Human Physiology," 1875-88; "Handbook of Physiology," 1905.

2. The Carnivorous and Herbivorous Types in Man; the Possibility and Utility of Their Recognition. II. Certain General Considerations. J. Bryant.
3. Pneumococcic Arthritis, with Report of Six Cases. J. W. Sever.
4. A Preliminary Report of the Results of Wassermann Tests as Reported from Different Laboratories, Calling Attention to a Little Knob on the Frenum of the Upper Lip, Which May or May Not Be Characteristic of Syphilis. O. D. Phelps.
5. The Femur of an Idiopathic Epileptic. J. S. Foote.

1. Correction of Foot Deformities from Poliomyelitis.—H. W. Marshall and R. B. Osgood studied the late results of this treatment in twenty-six cases selected from among many patients treated at the Massachusetts General Hospital. All simple tenotomies of the tendo Achillis for equinus deformity, all plantar fasciotomies for slight contractions of the feet, all recent cases of all sorts were discarded and only the more complex ones of longer duration retained. All patients within this restricted class, however, that came back for final observation are included, both good and bad results. The average length of time that has elapsed since operative interference among the twenty-six cases reported is four years and ten months. Twenty-three patients from the total number of twenty-six were distinctly improved after their surgical experiences. Poor as some operations appear to be at first glance, when judged from this standpoint, nevertheless they usually show increased usefulness if compared with previously more deplorable conditions that existed in each instance. There were no overcorrections of deformities following tendon transplantations in this series, the usual result being partial correction accompanied by

some functional improvement and with only occasional perfect success and complete restoration of function. These late conditions indicate in a general way what may be expected from surgical treatments of fairly complicated infantile paralysis cases in a large hospital where there are a number of different operators and division of responsibilities in the after-care of patients. These statistics, however, are far too meager and incomplete to possess weight in comparison between individual control of patients from beginning to end and cooperative direction of treatments by groups of physicians.

3. **Pneumococcic Arthritis.**—J. W. Sever reports a series of six cases representing various methods of infection by the pneumococcus, namely: (1) From the mouth by way of a tooth infection. (2) By trauma without previous known pneumonia. (3) By a previous pneumonia followed by an otitis media. (4) By trauma followed by pneumonia and involvement of the joint in nine days. (5) Following several attacks of bronchopneumonia and immediately after an acute attack of otitis media. (6) Involvement of joint two weeks after an acute attack of lobar pneumonia. This case represents the only typical one. All these cases had the diagnosis confirmed bacteriologically except Case 4, which, however, is included in this series on account of the improbability of its being anything else. The fluid in all these cases was rather thin and greenish yellow when the joint was first opened, but as it continued to drain at the time of the operation the heavier pus escaped. It was during this period that the fibrin flakes were expressed. The mortality was three out of six cases, 50 per cent. The joints, so far as the author has been able to determine, are practically normal in the two cases he has been able to follow.

4. **Wassermann Tests as Reported from Different Laboratories.**—O. D. Phelps has made it a practice to submit specimens of blood for examination to several laboratories. He tabulates the results obtained in the case of 358 specimens as follows: Four laboratories: Of 113 bloods 68 agree; 45 disagree; 60.2 per cent. agree and 39.8 per cent. disagree. Three laboratories: Of 135 bloods, 70 agree; 65 disagree; 51.9 per cent. agree and 48.1 per cent disagree. Two laboratories: Of 110 bloods, 72 agree; 38 disagree; 65.5 per cent agree and 24.5 per cent. disagree. In view of the above facts, one might well question the reliability of the test. The varying results reported in the literature from different laboratories and a chance difference in the report of a Wassermann in the experience of the author are what stimulated this comparison. The above results simply show the delicacy of the test and how susceptible it is to variation in technique, and to differences in the blood as taken at different times.

1. **The Effects of Tobacco and Alcohol upon the Cardiovascular System.**—By R. N. Willson. (See page 543.)

2. **Present Knowledge of Tuberculosis.**—Mary E. Lapham states that this knowledge has hardly begun. The evolution of the tubercle bacillus needs to be studied; the work done only shows that this or that species of acid-fast bacilli is not pathogenic for this or that animal; the path one needs to follow is the effect of adaptation to the host that has conferred upon the different tubercle bacilli their distinguishing characteristics. There is needed a scientific study of acid-fast bacilli and their activity in butter, milk, cheese, blood, feces, and urine. Where do smegma bacilli stand in the scheme of evolutionary development is another question to be answered. Remembering that life begins under watery conditions, and that marsh gas is the basis of all fatty compounds, one should go out into the marshes to find the origin of this group of bacteria which have learned to synthesize fats and have thus distinguished themselves from all other groups.

5. **Endameba Buccalis and Alveodental Pyorrhea.**—G. C. Brunelle and G. Ginsberg point out that the *Endameba buccalis* has not yet been cultured and in consequence Koch's postulales have not been fulfilled as regards the etiological relationship of the microorganism to alveodental pyorrhea. It is asserted by Bass and Johns that *Endameba buccalis* is primary in its attack, that the countless other organisms present are secondary invaders, and that the endameba is not present in normal mouths. Others take the opposite view, regarding the endameba as a possible secondary infective agent sometimes present in normal mouths. In an investigation of the frequency with which the endameba is present in normal mouths the authors' results follow very closely those reported by Bass and Johns. Thus, of 123 mouths showing no apparent lesions, three (2.5 per cent.) gave positive results, while of 107 cases of frank pyorrhea, 102 (95 per cent.) gave positive findings. In thirty-seven mouths showing a pyorrheal tendency *Endameba buccalis* was found in twenty-nine (79 per cent.) upon first smear, while in a series of thirty-nine cases referred by dentists who went directly into a pus pocket with a dental scraper for material to be examined, 100 per cent. positive results were obtained. These investigations show that *Endameba buccalis* is almost constantly present in pyorrheal conditions and is rarely present in healthy mouths.

8. **Posture and Arm Movements in Deep Breathing.**—J. F. Rogers notes that for the production of a maximum expansion of the lungs many teachers of physical training and physicians have recommended certain postures to be assumed and certain arm movements to be executed during inspiration. The standing position has been most used for the taking of breathing exercises, but the supine position has also been highly recommended. In both of these postures it has been taught that, for the greatest intake of air, the arms should be raised forward to the horizontal position, or sideward to the same level, or forward and upward, or sideward and upward. Still further to deepen or widen the chest it has been suggested that the person stand, or lie on his back, grasp the handles of pulley weights, the pulleys of which are attached to the floor at the feet of the breather, and, while inspiring, draw the handles of the weights forward and upward, as in the movements of the arms without the weights. The author's investigations show that whatever other effects there may be from the postures assumed and exercises carried out for purposes of deep breathing, there can be no advantage from them so far as increasing the intake of air is concerned. Deep breathing exercises are recommended for the tuberculous, and it is not long since these same arm movements as an aid to breathing

were prescribed for patients by a leading authority on the subject of this disease. As the arms are not without weight, their lifting is not done without considerable muscular exertion and the fatigue of these exercises is added, without result so far as the effect on deep breathing is concerned. With very deep inspiration there is a drawing backward of the head and a straightening of the thoracic spine—in other words, the assuming of the very erect posture, and, if any exercises are to be carried out as aids to a deep intake of air, it seems that the drawing backward of the chin and the assumption of the most erect standing or sitting posture would be most useful as an aid or accompaniment of deep breathing.

9. **Neosalvarsan in Treatment of Paresis.** — C. F. Read has treated twenty cases of paresis with 123 subarachnoid injections of neosalvarsan, in doses ranging from 0.003 to 0.006 gram diluted in at least 10 c.c. of the patient's own spinal fluid. During the treatment three patients died, but of these, two were in the final stages and death could not be fairly attributed to the treatment. One case, already slightly spastic when received, became intensely spastic and died with symptoms of motor tract degeneration. Two patients suffered incontinence. A few complained of weakness, headache, and leg pains from time to time after treatment. A number at various times had a slight rise in temperature for a short time after treatment. One case developed a Charcot joint during treatment. One patient had convulsions following a treatment but has had others not connected with the treatment. The Wassermann of the blood serum in nine cases (not tested in the remainder) remained 4+. In two cases it is now negative but in one it was negative before treatment and in the other it was not tested. One negative and one faintly positive Wassermann in the spinal fluid have become strongly positive. The above are the unfavorable results. The favorable results are the following: One case has entered a fair remission but still shows positive fluid findings. Another is improved markedly but is still very evidently paretic. A number show improved conduct or physical health which may possibly be the result of hospital care. In three cases the Wassermann in the spinal fluid has become weaker. From the foregoing results the author concludes that the subarachnoid treatment with neosalvarsan in small quantities is without effect and that when pushed with the object of obtaining results it is extremely apt to prove injurious. Its use in this manner is to be discouraged.

10. **Treatment of Rigid Scoliosis.**—E. Kleinberg finds that the very mild cases of rigid scoliosis can be satisfactorily treated by gymnastic exercises of one type or another and preferably by the Teschner system. The very severe types of scoliosis cannot be corrected or even satisfactorily changed by any known procedure. In the moderate types of rigid scoliosis more frequent and more marked improvement can be obtained by the Abbott than by the older methods. The author has devised a brace which is said to effectively apply the Abbott method and reduce the number and severity of the complications that are met with in plaster jackets. The earlier the treatment is begun the better are the prospects for improvement. The patients must be kept under observation for a long time to insure the permanency of whatever degree of improvement has been obtained.

2. **Intestinal Adhesions.**—By W. B. Brinsmade. (See MEDICAL RECORD, July 3, 1915, page 40.)

3. **Acanthosis Nigricans as Indication of Internal Malignancy.**—A. J. Markley states that the development of acanthosis nigricans in the adult is an indication of some serious internal disorder, the most frequent of which is cancer. The frequency of this association justifies the assumption of a diagnostic relation between the two conditions. Notwithstanding its rarity, acanthosis nigricans should be promptly recognized, and an effort made to locate and, if possible, to remove the associated malignant growth.

8. **Transverse Incision in Appendicitis.**—A. E. Rockey first advocated this method in an article in the MEDICAL RECORD in November, 1905, entitled "Transverse Incision in Abdominal Operations." In the region of McBurney's point, the fibers of the internal oblique and the transversalis run directly transverse, and the external oblique is only an aponeurosis. The aponeuroses of these muscles are united at their insertion at the border of the sheath of the rectus, the fibers of the broad tendons becoming a part of the sheath. This junction is the key to the situation in this operation. The skin incision at the place of election is made directly transverse with its center on McBurney's point, though it may be lower if conditions require. While the favorite anatomical situation permits easy access through a short incision, which may be desirable in children, or small persons with thin abdominal walls, the incision in ordinary cases should be 2 or 2½ in. in length and may be longer as the case requires. Continuing deeper, it passes through the outer part of the sheath of the rectus, severing the tendinous border and the aponeurosis of the muscles on a directly transverse line. When this is done, the handle of the scalpel may be inserted below, and the finger above, and the wound spread wide open by a single pull. Not a muscle fiber is cut. The fibers of the internal oblique and transversalis separate in a transverse direction. The aponeurosis of the external oblique is broader than that of the other muscles, thus permitting the incision through this to be carried further to the outer side. When the muscular part is reached, the spreading pull separates the fibers obliquely upward. The muscle is, however, as elastic as rubber, and the retractor, which is at once inserted, drawing outward, readily brings it into the transverse line. The rectus is now drawn back into its sheath at the inner side by another retractor. The peritoneum is divided on the transverse line. This incision is said to give a splendid exposure but is not adapted to pelvic operations. If doubt exists as to the differential diagnosis between the appendix and the tube or the appendix and the gall-bladder as the site of trouble the vertical incision is preferable. In the occasional case, when the appendix is adherent in the pelvis, a preoperative diagnosis can usually be made.

9. Right-Sided Postoperative Hypertension.—F. F. Simpson finds that right-sided hypertension occurs as a postoperative complication. It is usually slight and causes no alarming symptoms. It occasionally causes a circulatory disturbance but always with a rapid pulse. In rare instances it goes on to dilatation of the right auricle or even of the whole heart. It is more likely to occur when the myocardium is weakened by disease. It may readily be precipitated or intensified by excessive ether, or a prolonged extreme Trendelenburg position, or by the rapid intravenous injection of large quantities of salt solution while the heart is already embarrassed. It should be promptly recognized and treated by slight elevation of the head of the bed, a little morphine and cardiac stimulants.

7. The Public Health Work of the British Medical Association. H. Jones.

1. Treatment of Gunshot Wounds by Excision and Primary Suture.—H. M. W. Gray enumerates the following advantages of this method: Healing by first intention is assured in the vast majority of properly selected cases. Much time is thereby saved. Some wounds, which would otherwise require months to heal, are soundly united in the course of ten to fourteen days. The soldier is thus available for duty again at a much earlier date. The amount of attention required to be given by the medical officers and nurses is greatly reduced. Much pain is avoided. The amount of dressings required is reduced to a minimum, and in this way expense is lessened. Complications which may arise from the presence of a septic wound are avoided. A more sightly scar is obtained. Because of the absence of contraction which would accompany the formation of a large cicatrix, there is less impairment of function in the part concerned. In the case of head injuries, excision of the wound, especially in some, apparently trivial injuries, provides a means of ascertaining, with greater certainty than by any other method, whether depressed fracture or injury to the brain coexists.

3. Use of a Sleeve of Vein in Nerve Suture.—A. Fullerton has been using for a number of years portions of vein in nerve suture in the following manner: The most suitable vein for nerves of the upper extremity—as, for instance, the musculo-spiral, the median, and the ulnar—is the basilic vein at a spot between its commencement and the point at which it pierces the deep fascia of the upper arm. A segment of the vein about 1½ or 2 inches in length is excised and threaded on a sinus forceps. One end of the nerve is then caught by the forceps, and the sleeve pulled over. The ends of the nerve are then freshened with a sharp scalpel and sutured with fine catgut. When the suture is complete the sleeve is pulled over the junction and fastened to the nerve sheath by a few points of suture. The vein thus applied is intended to form an aseptic sheath for the nerve to keep the ends in secure apposition, to direct the growth of the new axis cylinders, and to prevent the ingrowth of scar tissue from the outside. Any vein of suitable size will do, and in the lower extremity a portion of the internal or external saphenous will probably be the most convenient. The sleeve must be pulled over the first nerve end before trimming.

August 2, 1915.

Etiology of Typhus.—The most striking feature of a paper on this subject by Proescher of Pittsburgh is the total absence of any allusion to the work of his fellow countryman, Plotz of New York, although numerous references to the labors of others in the field are interpolated. The paper is brief, a preliminary essay, and, aside from the bibliographical allusions, wholly technical. The parasitic cause of the fever according to the author's researches is a diplococcus appearing also as a diplobacillus which proliferates originally in the endothelia of the blood vessels. It probably reaches these cells through the proboscis of the louse. Blood smears show the presence of detached endothelia in which may be seen numerous parasites, both forms occurring side by side. This find is in full accord with the histological diagnostic discovery of Eugen Fraenkel, who observed peculiar alterations in the small cutaneous arteries of typhus patients. While a peculiar specific lesion it suggests somewhat a periarteritis nodosa, since in both there are nodular proliferations which cause obstruction of the arterioles. The lesions are strictly microscopic. It seems unquestionable that the multiplication of the bacteria takes place in the endothelia alone, not in the blood stream. The infected endothelia are exfoliated into the latter in large numbers. Apparently the author has been unable to cultivate his microorganisms, while Plotz has, we believe, not only been successful in this respect but has elaborated a therapeutic serum. The author regrets that he cannot claim to have discovered the exciting cause of typhus, but hopes to be able to complete his work in due season.

Treatment of Gunshot Fractures.—Pincus states that the enormous war material of these injuries makes the establishment of indications a necessity. Gunshot fractures differ from the complicated fractures of peace times because they do not come to treatment nearly so soon. The former belief that gunshot fractures are not *per se* infected, and become so chiefly as a result of probing, etc., no longer holds good. Two cases are cited of soldiers who reached the reserve hospital simultaneously with the same type of injury and same first-aid dressings. One of these presented a fulminating gas gangrene while the other was virtually sterile. As a rule in the complicated fractures of peace times we see bone fragments driven outward through the soft parts, while in gunshot fractures shell fragments and shreds of tissue are forced into the tissues. The long period of transport—three or four days is the minimum—has effectively robbed the soft tissues of their elasticity and the muscles undergo marked retraction, so that extension of limbs meets with great resistance. The main question in the treatment of gunshot fractures is not "How can we most ideally replace the fragments from the anatomical viewpoint?" but "Is the wound infected, and if so, in what degree?" The latter is by no means easy to answer. High temperatures need not mean great virulence. Many a case received as "septic" because of the temperature proves to be aseptic after reposition of the fragments. Phlegmons may cause no further trouble, even when unopened, when the wound canal is properly drained through fenestrations in the immobilizing dressings. If the temperature does not subside after two days an artificial opening may replace the natural one. If a joint cavity is exposed by the wound it furnishes no necessary contraindication to drainage as above outlined. The author has seen a joint (wrist) thus treated heal with perfect mobility. The old circular plaster-of-Paris bandage applied under strong extension (Bergmann) has regained during the present war all the favor which it may have lost in recent years.

Bardenhauer's extension method is too elaborate for military surgery, and nail extension appears to be contraindicated in all infected or possibly infected fractures.

Münchener medizinische Wochenschrift.

August 3, 1915.

Epidemic Meningitis in Soldiers.—Klinger and Fourman describe an epidemic of cerebrospinal meningitis which lasted from February to April, 1915. It occurred in the barracks of some Swiss troops which naturally had not been exposed to the hardships of actual warfare. The number of soldiers attacked was eleven, while but two civilians in the near-by residence district developed the disease. Forty-two other soldiers who had been exposed were quarantined and six of these who were found to be carriers were isolated. Those classed as suspected carriers were not isolated. A large number of soldiers who had not been exposed were also examined and were found to include a small number of carriers. The authors were in fact able to corroborate the experience of others that mere isolation of carriers has no influence on the course of an epidemic. The so-called suspects were men who had suspicious-looking cocci in their throats, which organisms, however, failed to answer to all the requirements of the meningococcus. On the other hand in certain cases of clinical meningitis of classic type the cocci fulfilled all requirements save that they would not form colonies in fermenting maltose. While believing that isolation furnishes no certain prophylaxis the authors would not abandon it, for the moral effect is good. The public would not understand why those attacked by any dread infectious disease should be spared this precaution. If it is omitted the public would clamor against isolation for the less deadly diseases.

Indicanemia.—Haas refers to the original discovery of indican in the blood of uremic patients by Obermayer and Popper. Their observations were promptly confirmed and soon afterward it was learned that indican could be present in the blood in both acute and chronic nephritis when there were no evidences of impending uremia. It is now acknowledged that indicanemia is rather an unfavorable prognostic in chronic nephritis, or, in other words, is evidence of a certain degree of renal insufficiency. The author decided to study the subject of indicanemia anew on two cases of chronic nephritis. One patient had cirrhotic kidneys with high blood pressure, while the other had ordinary chronic parenchymatous nephritis with blood pressure normal and much albumin in the urine. Both patients had indicanemia and in both the residual nitrogen was still normal. It therefore became evident that the presence of indican in the blood antedates azotemia as evidence of future mischief, and the more delicate and trustworthy the test for indican in the blood the greater the promise for a prognostic resource. Also of great importance is the ratio between residual *N* and indican in the blood. The amount of the aminoacid fraction of residual *N* may also be looked on as representative of the degree of renal insufficiency, and the ratio of aminoacids and indican in the blood should furnish another criterion of that condition. The rest of the paper is devoted to a study of Jolles's indican reaction.

Tangential Shots of the Thoracic Cage.—Burckhardt and Landois go into this subject at great length. While these injuries do not constitute an entity they differ in a number of respects from penetrating wounds. Almost invariably more than one rib is involved in the tangential form. From the course of the wound through fractured ribs and muscles infection also occurs more readily in the latter, as does likewise open pneumothorax with resulting empyema. The respiratory mechanism is badly damaged and bilateral affections of the lungs often result. The projectiles cause contusions of the viscera, not only the lungs but the liver and kidneys; some of these are accompanied by lacerations, and hemorrhage and necrosis occur. Naturally, tangential shots of the lower ribs have more of these complications. These injuries will in time lead to new viewpoints in regard to diagnosis and indications for treatment, notably surgical.

Percussion in the Diagnosis of Apical Tuberculosis with Special Reference to Krönig's Apex Field.—Schneider refers to Krönig's original claim that percussion is of much more value than auscultation in the earliest recognition of tuberculosis of the apex. The former may be so carried out as to reveal the existence of a true focus of disease while auscultation discloses only the presence of a catarrhal process, not necessarily tuberculous. In true apical tuberculosis the apex has become more narrowed and smaller. Percussion shows this both in vivo and on the cadaver. Cadaver control is of course out of the question in routine work, but *x*-ray control is fairly useful. The author now relates his own experience with Krönig's alleged apical field in which narrowing and general diminution are recognized by percussion and comes to the conclusion that auscultation is of more value in early diagnosis while percussion a la Krönig is to be used with great caution with reference to shortened resonance and slight narrowing (both in the right apex). Again, absence of these finds cannot exclude the presence of tuberculosis. Cases of the latter may present moist râles on auscultation and nothing at all on percussion. It may be laid down that as soon as percussion finds are obtainable, *x*-ray finds are simultaneously obtainable.

Veronal-Bromine Synthetics.—Serejski describes a new synthetic which consists of a veronal with a side chain of dibromopropyl. The bromine content is over 40 per cent. As is usually the case no reasons are adduced to show the superiority of the synthetic over a simple combination of veronal and bromides. It is a nerve sedative and mild hypnotic, and has given excellent results in psychoses and psychoneuroses attended with excitement. It appears to be readily taken and without the development of untoward collateral and after effects. Thus far, when administered daily no cumulative effects or habit-forming tendency has been noted. The cost per diem is about one mark or about twenty-five cents in Germany. When the excitation is of the crescendo type the remedy has been powerless to check it. In cases in which failure occurs, opiates may also fail to obtain the desired results. Whether it can rival opium in depressive cases has not yet been decided. Any remedy which is a nerve sedative is incidentally a hypnotic whenever the wakefulness is due to motor unrest. From this viewpoint the new synthetic is not an essential hypnotic. Sedatives of this type often render the use of the latter unnecessary. The drug was sufficiently powerful in one case to quiet a depressive with impulsive ideas.

Hot-Air Therapy in Gynecology.—Professor Walther of Giessen sums up this subject as follows: The diagnosis must be beyond doubt and exact and patients must have been interned—they should never be treated in dispensaries. If the physician cannot give complete supervision to the case he must detail a competent person to represent him by constant attendance. No complications must be present, as fever, suppuration, hemorrhage, etc. The principle involved in this form of treatment is active hyperemia and the indications include all chronic inflammations and congestions.

Insurance Medicine.

Blood-Pressure in Life Insurance Examinations.—Dr. Claude C. Cody, Jr., says that the earlier studies in this field were all on arterial pressure, while venous pressure to this day has been neglected. Several factors of prime importance are not constant, and, therefore, the normal venous pressure has great variations due to changes in the atmospheric temperature or pressure. Consequently the venous pressure is not now, and probably will not be in the immediate future, of any value to us in life insurance examinations. The determination of the arterial or blood-pressure is encumbered with no such difficulties, and the results are of great value from a prognostic standpoint in life insurance work.

In studying the technique of blood-pressure the prime factors of importance and which are under our control are the posture of the patient, his mental attitude, and the instrument. The patient should be seated in a chair with his arm resting upon a table. The mental attitude of anxiety or intense curiosity may be sufficient to cause a rise in blood-pressure of 20 mm. This curiosity may be overcome by telling the patient that three or more readings will be necessary.

Blood-pressure may be obtained by either the auscultatory or the palpatory methods. The former has a double advantage over the latter, due to greater accuracy and the ability to determine the diastolic pressure. The auscultatory readings are uniformly higher than the palpatory. The technique of the auscultatory readings is as follows: After the arterial pulsation has been eliminated the stethoscope is applied over the artery, with a gradually decreasing pressure in the arm cuff, and the reading is noted at the first sound, usually a click or clicking murmur. Following this there is a series of sounds which Ettinger, in 1907, separated into five phases and named in the order of their occurrence. The first phase marks an interval of clear tones which is soon replaced by the second and third. The second phase marks an interval of muffled tones with a series of murmurs. The third phase marks an interval of clear, frequently booming tones which suddenly cease. The fourth phase marks an interval of dull tones. And the fifth phase marks the disappearance of all sounds. The first, second, and third phases are always clearly marked, occasionally some difficulty will be experienced in differentiating between the third and fourth. In this case the point of the disappearance of the third phase can be readily determined by lowering the blood-pressure until the sound disappears, then gradually increasing it when the dull tone of the fourth phase is audible, followed almost instantly sometimes by a clear, loud tone which marks the end of the third phase. It must be plain though that the distinction between the various phases is clear only over normal arteries and those which are but slightly sclerosed; and, also, when the heart beats are regular in force and rhythm. The determination of the precise point of diastolic pressure is the subject at present of more discussion in the technique than any other. Korotkoff, in his original communication on the auscultatory method in 1905, stated that the diastolic pressure was marked by the change from the clear third tone to the dull fourth—in other words, at the end of the third phase. This is the generally accepted fact.

The heart must always lift a certain load equal to the peripheral resistance before the aortic valves will open. From the moment the valves open pressure forcing the blood toward the periphery is represented by the force exerted by the heart from the opening of the valves till the close of the systole. Thus, the diastolic pressure represents the peripheral resistance and the pulse-pressure represents the actual propulsive force in the arteries. The normal diastolic pressure is between 80 and 90 mm. with 70 and 100 as the limits; the normal pulse-pressure is 40 and 30 and 50 mm. as the limits.

In conclusion it can be stated that: (1) Venous pressure is of little value. (2) The posture, mental attitude, and instrument are important. (3) The auscultatory readings are 5 to 8 mm. higher than the palpatory. (4) The auscultatory method is better than the palpatory. (5) The diastolic pressure should be read off the scale at the end of the third phase and not at the disappearance of sound. (6) Since the diastolic pressure measures the peripheral resistance it is a better index of hypertension than systolic pressure. A sustained diastolic pressure of 100 to 110 indicates hypertension. The diastolic is less influenced by physiological factors than the systolic pressure. (7) The pulse-pressure measures the energy of the heart in systole in excess of the diastolic pressure. Clinically it is the load of the heart and is approximately 50 per cent. of the diastolic pressure. (8) Marked variations within short intervals in pulse pressure observations should make one think of a neurotic cardiac element. (9) The blood-pressure determination is worth all the trouble it takes from a prognostic or life insurance standpoint.—*Texas Medical News.*

Group Insurance for a Street Railway Company.—The Brooklyn Rapid Transit Company has made an arrangement with a large insurance company whereby all of its employees who have been two years or more with the company may insure under the so-called "group" plan. Those eligible number about 8,000. Any employee may take insurance up to $5,000, subject to the usual examination, but if as many as 5,000 apply under the plan the examination requirement will be waived. The company agrees to pay one-half the annual premium on insurance up to $1,000 and the entire premium in the case of those who, after taking out insurance, are retired under its pension system and also in the case of those who after ten years' service have had their earning capacity reduced through partial disability.

Scope of Medical Examiner's Authority.—A certificate issued by a fraternal insurer, which was referred to in the application, provided that no local officer or employee was authorized to waive any of the conditions of the certificate or by-laws. In an action on the certificate it was held that a medical examiner, by falsely answering questions in the application, which was signed by the applicant, and which declared that the applicant warranted the truth of all representations therein, could not estop the insurer from relying on the falsity of such representations to avoid the policy; such action being without the scope of the examiner's authority.—Sovereign Camp v. Lillard (Tex.) 174 S. W. 619.

Book Reviews.

GAS POISONING IN MINING AND OTHER INDUSTRIES. By JOHN GLAISTER, M.D., D.P.H., F.R.S.E., Professor of Forensic Medicine and Public Health in the University of Glasgow, and DAVID DALE LOGAN, M.D., D.P.H., Surgeon to the Coltness Ironworks, Newmains. Price, $3.50 net. New York: William Wood & Company, 1914.

GAS poisoning, that is, essentially, poisoning with carbon monoxide, is one of the most important industrial poisonings, not only because of the numerous industries in which it is met, but also because of the insidious onset of the poisoning as it often occurs. This is, as far as we know, the first volume of any size to be devoted wholly to this subject. The literature, though extensive, is scattered and this work is therefore all the more welcome. The authors have handled the subject in an extremely interesting and efficient manner. There is a thorough discussion of the way in which carbon monoxide may arise in the various industries and how it may be dangerous to relatively distant individuals. The chapters on symptomatology and pathology and on methods of detecting carbon monoxide are complete and excellent. It is reassuring to see the importance with which the authors view the chronic form of poisoning. It was not generally recognized in this country until comparatively a short time ago. It is very interesting to read of the prominence which is given to the use of oxygen in the treatment of the poisoning. Its necessity is clearly shown in spite of the adverse criticism that has been offered during the past few years. There are also a complete description of the various forms of rescue apparatus now obtainable and a bibliography of a dozen pages. The only criticism that might be made is that there is more or less confusion in the arrangement of the chapters which do not follow in any logical sequence. The book is an exceedingly valuable, as well as interesting one and should be in the possession of every man who is apt to come into contact with cases of poisoning with carbon monoxide.

PYELOGRAPHY (PYELO-URETEROGRAPHY). A Study of the Normal and Pathologic Anatomy of the Renal Pelvis and Ureter. By WILLIAM F. BRAASCH, M.D., Mayo Clinic, Rochester, Minn. Octavo of 323 pages with 296 pyelograms. Price, cloth, $5.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

WHILE Voelcker and von Lichtenberg of Heidelberg, first succeeded in demonstrating the outline of the human renal pelvis and ureter by pyelography in 1905, but little use was made of this procedure until Braasch recognized its possibilities in the diagnosis of renal and ureteral conditions and, through the publication of his observations, drew the attenton of surgeons throughout the world to its value. To Braasch, then, belongs much of the credit for the rapid development of this most important diagnostic aid; hence a thorough exposition of the subject, such as we have here, has unusual value when coming from him, particularly since the 296 pyelograms, which serve to illustrate points made in the text, are culled from several thousand made at the Mayo Clinic during the past five years, and upon which his experience is based.

The work is divided into ten chapters having the following headings: The History of Pyelography with Bibliography; Technic; The Normal Pelvis; Abnormal Position; Mechanical Dilatation; Inflammatory Dilatation; Renal Stone; Ureteral Stone; Renal Tumor, and Congenital Anomaly.

The first forty-six pyelograms are said to represent the outlines of normal pelves and, in many instances, normal ureters also; yet upon carefully looking these over one cannot fail to be impressed with the great variation in conformation of the forty-six pelves which the author classifies as normal, and there are several which bear a very close resemblance, at least, to pyelograms of supposedly pathological pelves and ureters shown in later sections of the book. Some of these apparent anomalies are explained on the ground of incomplete, and some of overdistention. The reviewer can hardly doubt the correctness of the author's interpretations, hence would emphasize the fact as pointed out by Braasch in his preface that "the interpretation of the great variety of pelvic deformitis outlined in the pyelogram is difficult and is possible only through familiarity with the various types," and would add that a knowledge of the clinical history of the patient and details of the technique employed in the individual case are often a *sine qua non* for correct interpretation of the plate.

Braasch has made many valuable contributions to current literature on this subject, but in presenting this book with its store of pyelograms and explanatory notes, minute details of technique, and other valuable features, he has combined in convenient form an epitome of the subject that will well repay careful study even by the expert; while to the novice the book should be well-nigh indispensable.

NOTES ON DENTAL METALLURGY. For the Use of Dental Students and Practitioners. By BRUCE HEPBURN, L.D.S. (Glasgow). Lecturer on Dental Metallurgy and Visiting Dental Surgeon in the Glasgow Dental Hospital and School. Second edition. Price, $2.25 net. New York: William Wood & Company, 1915.

THIS book of notes on dental metallurgy was compiled by Mr. Bruce Hepburn for the use of dental students preparing for dental qualifications and degrees in English speaking dental schools. This, the second edition, has been carefully revised, much of it rewritten and generally brought up to date. The chapter on alloys has been written by Professor A. Campion of the Royal Technical College, Glasgow. The book should be extremely useful to dental students.

WAR SURGERY. By EDMOND DELORME, Médecin Inspecteur Général de l'armée. Translated by H. de MÉRIC, Surgeon to In-patients French Hospital, London. With illustrations: price, $1.50 net. New York: Paul B. Hoeber, 1915.

As a surgeon Edmond Delorme has a world-wide reputation, and his present position has afforded him exceptional opportunities for seeing under the most advantageous circumstances the surgery of modern warfare. He has taken full advantage of the opportunities and has produced a book which, although small in size, is replete with useful information. An interesting feature of the book, is the testimony of the author to the value of hydrogen peroxide in the treatment of wounds and especially in the treatment of gas gangrens and tetanus. The translator Mr. de Méric is to be commended for his excellent work. The book should prove instructive to army surgeons.

THE MEDICAL CLINICS OF CHICAGO. Published bimonthly. Price, $8.00 per year. Philadelphia and London: W. B. Saunders Company.

THIS is a new publication which is to be devoted entirely to Internal Medicine. The subjects are to be presented in a clinical way and are to represent the leading hospitals of Chicago. In the first number, cases are presented by Drs. Charles L. Mix, Charles S. Williamson, Isaac A. Abt, Robert B. Preble, Maurice L. Goodkind, Frederick Tice, Walter Hamburger, and Ralph C. Hamill. Many of the cases are interesting and it may be that there is a place in medical literature for such a publication. It seems to us, however, that the attempt has been made to present too many cases, a fault too frequently found in all clinics. There are some twenty cases presented in about 200 pages, and the inevitable result is that in some instances the consideration seems to be rather superficial. What there is, is well done and there are many excellent illustrations. These latter probably account for the rather high price that is asked. It is probable, however, that the publication will be popular and we may say that this first number is interesting enough to deserve popularity.

SWANZY'S HANDBOOK OF THE DISEASES OF THE EYE AND THEIR TREATMENT. Edited by LOUIS WERNER, M.B., F.R.C.S.I., Sen. Mod. Univ. Dub., Surgeon to the Royal Victoria Eye and Ear Hospital, Onhthalmic Surgeon to the Mater Hospital, Professor of Onhthalmology, University College, Dublin, and Examiner in Onhthalmology, Dublin University. Eleventh Edition. With Illustrations. Price, $4.00 net. Philadelphia: P. Blakiston's Son & Co., 1915.

AN eleventh edition of a work requires little laudation. This, however, is the first edition which has appeared since the death of Sir Henry Swanzy. Dr. Werner, than whom no more fitting or capable editor could have been found, has made no change in the general plan or character of the book. The text has been revised and brought up to date and a considerable amount of new matter has been incorporated. The result is that in its present form Swanzy's Diseases of the Eye is one of the best books of reference extant. It is adequately illustrated.

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-seventh Annual Meeting, Held at Lakewood, N. J., May 24, 25 and 26, 1915.

THE PRESIDENT, DR. GEORGE N. ACKER OF WASHINGTON, D. C., IN THE CHAIR.

(*Concluded from page* 505)

The Reducing Substance in Spinal Fluid.—Dr. OSCAR M. SCHLOSS and LOUIS C. SCHROEDER of New York presented this communication which was read by Dr. Schroeder. They stated that in order to obtain additional evidence concerning the nature of the reducing agent in spinal fluid they had made a series of quantitative determinations in three specimens of cerebrospinal fluid, from 400 c.c. to 600 c.c. each. The specimens were precipitated with alcohol and evaporated to small bulk in slightly acid solution. This concentrated solution was dextrorotatory and a comparison of the quantity of dextrose calculated on this basis with a determination by Benedict's quantitative copper solution were in close accord. The solution fermented readily with yeast and gave a typical osazone, insoluble in hot water, soluble in pyridine and melting at 200° to 210° C. A repetition of this procedure of Halliburton gave no precipitate of pyrocatechin. A further proof, a number of other observations were made which the authors described. The results of their examinations in twenty-six cases were tabulated and summarized as follows: The reducing substance in spinal fluid was a fermentable, dextrorotatory sugar, probably dextrose. In infants free from meningeal disease the spinal fluid sugar ranged from 0.05 to 0.134 per cent. approximately, the same figures which were obtained for blood sugar. In cases of meningism the spinal fluid sugar was normal while in epidemic cerebrospinal meningitis and suppurative forms of meningitis the sugar was greatly reduced or absent. A large proportion of the cases of tuberculous meningitis showed a decrease in the sugar of the spinal fluid. The decrease of sugar was only of diagnostic value in this disease. The reduction substance was not decreased in cases of idiocy, cerebrospinal syphilis, or anterior poliomyelitis.

Dr. ALFRED HAND, JR., of Philadelphia said he had carried out a number of examinations of spinal fluid and felt convinced that the reducing substance in the spinal fluid was a sugar, though his work had not been done as scientifically as that of Dr. Schloss. He was struck by the fact that something was absent in suppurative meningitis which was present in tuberculosis, so much so that he depended on it in making a diagnosis. In examining a spinal fluid the presence of sugar always stimulated him to a more thorough search for the tubercle bacilli.

Dr. HOOBLER asked Dr. Schloss' opinion with reference to the prognostic value of these findings and whether the injection of a serum that contained sugar caused an increase in the amount of sugar in the spinal fluid.

Dr. SCHLOSS said that with reference to the prognostic value of these observations, if sugar reappeared in the spinal fluid in a case of cerebrospinal meningitis, it was the best indication of improvement. They had observed a clnical improvement in a number of cases with the reappearance of the sugar in the spinal fluid together with a change in the amount of globulin and the number of cells. The sugar in the serum was so infinitesimal in quantity that it could not have much influence.

Acute Cerebellar Ataxia in Children.—Dr. J. P. CROZER GRIFFITH of Philadelphia presented this paper. He related the history of a female child, five years of age, in which the notable features were the rapid development of symptoms without discoverable cause unless possibly the child had suffered from influenza, the very uncommon degree of nystagmus, the taxia of the extremities, the disturbance of the sensorium, affection of speech, slight increase of reflexes, and the rapid recovery, completed within one month from the onset of the illness. These symptoms pointed chiefly to some disorder of the cerebellum, but that that was the only portion of the brain affected would seem questionable. The essayist reviewed the classification of Fickler with reference to cerebellar and cerebral affections and also discussed the seventeen cases of encephalitis which he had collected from the literature. He concluded from an analysis of these cases that as an apparent cause of the attacks infectious diseases were very evident, that a belief in the cerebellar origin of the disease was warranted and that there were other symptoms, as disturbance of the sensorium, unconsciousness, convulsions and delirium, all of which might be classed among symptoms common to intracranial lesion. There was a distinct tendency to increase of the reflexes in this series pointing toward the cerebellar involvement. The series also showed how frequently there might be a cerebellar ataxia without nystagmus. There was every reason to believe that in some instances very few, if any, evidences of the disease would remain; however, that severe symptoms might exist for a long time or always was shown by at least eight of the cases.

Foreign Body Pneumonias.—Dr. AUGUSTUS CAILLE of New York reported these cases, which he had observed at the Post Graduate Hospital during 1914. Two of the cases were seen in the wards, an outside diagnosis of unresolved pneumonia having been made without any suspicion of a foreign body in the lungs. The third case with a foreign body history. In the first case the spasmodic character of the cough, the expectoration of pus in an acute condition, and amphoric breathing aroused suspicion of the presence of a foreign body. The *x*-ray showed a large tack in the right lung, which their bronchoscopist succeeded in removing at a second attempt. Rapid recovery followed. The second case gave a history of unresolved pneumonia and spasmodic cough lasting a year. No pus was found on puncture but the *x*-ray showed a large nail in the left bronchus and partly in the trachea. Following the removal of the nail by a lower tracheotomy, an extensive pneumonia developed and the child died. In the third case a history of having swallowed a large brass shawl pin was given. The pin had been in the child's lungs forty-three days without causing inflammation. These cases served to teach that all cases of unresolved pneumonia and cases of pneumonia of atypical behavior should be *x*-rayed. Such cases should be reported in the lay press so that they would serve as a warning to those having the care of young children not to teach by example the bad practice of putting things in the mouth.

Dr. E. E. GRAHAM of Philadelphia said he had had three cases that came under the same category as those reported by Dr. Caille in that the possibility of the presence of a foreign body had not been suspected. The attention of the profession, too, should be called to the possibility of the presence of a foreign body in cases giving indefinite histories similar to those which Dr. Caille had reported.

Dr. D. J. MILTON MILLER of Atlantic City related the history of a boy who was admitted to the hospital with all the symptoms of lobar pneumonia in the right side. After three or four days the boy coughed up a tack and then made a speedy recovery.

Dr. KOPLIK cited two instances of foreign body in the lung somewhat similar to those already reported and said that if the *x*-ray did not reveal the presence of a foreign body in a case in which such a possibility was suspected it was advisable to make an examination with the bronchoscope.

Meningitis in the New-Born, with Report of a Case.—Dr. CHARLES HERRMAN of New York presented this report. He stated that meningitis in the new-born was rare. An incomplete search of the literature had brought to light only eight cases with post-mortem and bacteriological examinations. After reviewing these cases the writer said that his own case occurred in a child delivered normally at the Lebanon Hospital and who during his stay there presented no unusual symptoms. The day after leaving the hospital the baby was brought to Dr. Herrman's service in a cyanotic and apathetic condition. There were no symptoms suggesting the possibility of meningitis. The child's temperature became subnormal, cyanosis increased, breathing became irregular and the child died on the following day. Post-mortem examination by the coroner's physician, Dr. Riegalman, showed the presence of meningitis and cultures from the meningeal exudate showed the presence of the pneumococcus. This case was of particular interest because it was the only case of pneumococcus meningitis in the new-born that had been reported, and on account of the absence of fever and the entire absence of meningeal symptoms. Infection in these cases might take place through the placental circulation, by premature respiration, or at birth through an injury to the skull, or after birth, through the usual avenues, eyes, ears, throat, gastrointestinal tract, umbilicus, or genitals.

Dr. JULIUS P. SEDGWICK of Minneapolis expressed the opinion that meningitis was more common in the new-born than had been indicated. It was probably not recognized oftener because in a maternity hospital the baby was a secondary consideration. The ideal arrangement would be to have a pediatric department in connection with maternity hospitals. If the pediatrist had this opportunity to study the new-born he felt sure that many interesting things could be learned. Schauter had a pediatric department in connection with his clinic, but this was the only instance of this kind of which he knew.

Dr. KOKLIK said he had seen a number of cases of meningitis in the new-born. The infection was usually a streptococcus one in so far as he could remember, but in one case he had found a bacillus somewhat similar to that of typhoid. Many of these cases were diagnosed as sepsis.

Dr. L. E. LA FETRA agreed with the other speakers that meningitis in the new-born was more common than they had been led to believe. He had read a paper in which he had reported a number of such cases, and had recently seen another which he had not reported. The symptoms of meningitis might be taken for those of general sepsis in these cases. Sometimes the colon bacillus was the infecting agent, but he had also found a bacillus resembling the typhoid bacillus. In cases with a marked cyanosis a lumbar puncture might be advisable, not on account of the meningitis but on account of the possibility of hemorrhage which might be amenable to treatment.

Dr. HERRMAN in closing, also agreed that meningitis in the new-born might be more common than he had stated in his paper. Pediatrists should have the care and control of the new-born. All the cases which he had reported were under three weeks of age; if he had included those up to three months the number would have been greater.

A Case of Amaurotic Family Idiocy in One of Twins.—Dr. CHARLES HERRMAN of New York reported this case. He stated that the patient was twenty months old when first seen and presented the typical symptoms of amaurotic family idiocy. Some years ago Hirsch held that the changes in the central nervous system in these cases were caused by toxic substances which were present in the mother's milk. These infants received the mother's milk only two weeks and it was difficult to see why it was toxic for one child and not for the other. It was now recognized that amaurotic family idiocy was a typical example of a family disease. About 100 cases had thus far been reported; many more had not been recognized or reported. The writer had had eleven cases under observation during the past sixteen years. The essayist discussed the etiology of the condition and stated his reasons for believing that the disease was not any more common in the children of Russian emigrants than among others. The large number of patients among the children of Hebrew parentage could best be explained by the rôle played by consanguinity, and the mode of transmission could be explained on the basis of the Mendelian principles of heredity. The unit characters in the ancestry which were involved in amaurotic family idiocy were evidently of the recessive type.

Dr. HENRY KOPLIK of New York said that in a case in which amaurotic family idiocy was suspected, examination of the fundus of the eye with the ophthalmoscope would clear up the diagnosis.

Dr. HERRMAN said that in early infancy it was not so easy to make a diagnosis based on the condition of the eye as the eye changes were not so distinct at that time. Hirsch, he believed, had given up the idea that the mother's milk had anything to do with the condition. It was difficult to explain this case on a toxic theory since the two children had the same nourishment and the same environment. The disease was congenital but in some instances the child appeared to be normal until five months of age and then began to show symptoms.

General Tuberculosis, Including the Skin, in a Child.—Dr. WILLIAM P. NORTHRUP of New York reported this case, which he stated was similar to three previously reported by him. At the age of four months the child was taken with diarrhea and wasting. It had a cough but no vomiting and no crying. The skin eruption and the *x*-ray had enabled him to make the diagnosis of miliary tuberculosis. In a case of miliary tuberculosis a good *x*-ray, gave, next to an autopsy, the most intimate knowledge of the lesion in the child's lungs. The skin eruption in miliary tuberculosis furnished a pathognomonic sign for diagnosis, and such a lesion was almost always an indication that one was dealing with a fatal form of tuberculosis in young children. The characteristics of the lesions were that they were about the size of the rose spot in typhoid fever, were tipped by a tiny vesicle, surrounded sooner or later by a congested hemorrhagic zone with the form of a crust, which when removed, left a pit. In cases of acute tuberculosis these vesicles were the first revealed lesion.

Macewen's Sign.—Dr. HERBERT B. WILCOX of New York presented this paper which was based on observations made in Dr. LaFetra's service at Bellevue Hospital. Macewen's sign was best determined by placing the stethoscope on the forehead just above the base of the nose. The skull was then tapped with the percussing finger or the hammer, over the parietal region, beginning just over the parietal boss from which the percussing finger should approach to the point at which the stethoscope was applied. This should be carried out on both sides of the head. A typical sign observed in this way consisted in a high pitched, sharp, short, cracked-pot note. It was most distinct when percussion was being done over, behind, or below the parietal boss on either side, was unchanged as the point percussed passed downward, and diminished in intensity and character as the point percussed approached the stethoscope. The latter point was important in differentiating between a false and a true Macewen's sign as the reverse obtained in percussing a normal skull. The author emphasized the fact that increased clearness of sound when percussion was done over the posterior portion of the skull rather than near the stethoscope was diagnostic. The sign uniformly accompanied conditions of increased cranial tension and was not found unless this causative factor existed. It was equally applicable to infants and older children. It was presented in fifty of fifty-three cases of tuberculous meningitis; in seventeen of eighteen cases of meningitis of other types, and was found to vary directly with the development and recession of cerebral symptoms as complications of disease not directly affecting the central nervous system. It was present in eleven of thirteen cases of pneumonia in five of which lumbar puncture showed increased cerebrospinal fluid under pressure. The sign was uniformly lacking in children normal as to the brain and its coverings.

Dr. L. E. LA FETRA said that Dr. Wilcox should be congratulated on the persistence with which he had worked on this sign. He also reiterated the points to which it was necessary to give special attention in order to distinguish between the true and false Macewen's sign. This sign was important as indicating when one should draw off spinal fluid in cases other than meningitis.

Dr. KOPLIK said he had used Macewen's sign and found it useful in indicating the presence of fluid in beginning tuberculous meningitis and in serous meningitis due to otitis. Much depended upon the individual's ability to apply the method. The older the child the more valuable was the sign.

A Preliminary Report on Pneumonia in Children, with Special Reference to Its Epidemiology.—Dr. GODFREY R. PISEK of New York discussed the findings in 1,000 cases of pneumonia in children studied in the wards of the Post Graduate Hospital. A series of charts were presented showing the mortality and the results of plate culture of the sputum. After reviewing the work of Dr. Cole and that of Dr. Gillespie on the varieties of pneumococci and discussing the epidemiology Dr. Pisek summarized as follows: From a study of 1,000 cases a mortality of 43.3 per cent. was established. This was probably higher than was obtained in private practice among well-to-do people, but was the average for the mass of city dwellers. Bronchopneumonia was preeminently a disease of the first two years of life, and after the third year was relatively uncommon. Lobar pneumonia was the type of the disease which was present after the third year in practically all cases of pneumonia if those cases which were frequently secondary to some other condition or those in which the pneumonia occurred as a terminal condition were omitted. Lobar pneumonia *per se* was a common condition in the first and second years of life, being much more frequent than was commonly supposed. The infection which was the etiological factor in lobar pneumonia was always the pneumococci, while a bronchopneumonia might be due to a number of organisms such as the streptococcus or the influenza bacilli, occurring alone or as a mixed infection. If pneumococci were present in bronchopneu-

monia they were usually one of a group of organisms commonly found in the mouth. The pneumococci might be divided into four general groups, each being made up of many races which were closely related. By the method outlined a pure culture of pneumococcus might be obtained and the group determination completed within twenty-four hours from any given case of pneumonia. The division of the pneumococci into groups was of great importance from the standpoint of treatment, since a serum or vaccine prepared from organisms of one group could not be applied in the treatment of a pneumonia due to organisms of another group. It was hoped that the division of pneumonia into groups would eventually bring about the treatment by means of specific sera or vaccines, thus replacing the symptomatic treatment of to-day. A careful scrutiny of this series of cases failed to reveal any evidence of an epidemic, or even of a house infection.

Dr. E. E. GRAHAM of Philadelphia said that Dr. Pisek had stated that forty-one cases of lobar pneumonia out of the 1,000 developed empyema. His experience was that the percentage of empyemas varied from year to year. The mortality of 63 per cent. for empyema in lobar pneumonia which Dr. Pisek had found was certainly different from his experience, but it made a great difference whether the pneumonia occurred in hospital or private patients.

Dr. JULIUS P. SEDGWICK of Minneapolis brought out the point that the mortality from pneumonia was quite different in different parts of the country. In Minneapolis Dr. Barret reported a series of 125 cases of lobar pneumonia without a death. He had had thirty-six cases with only one death and that occurred in an old man who had complications. In Minneapolis, the mortality of pneumonia in infants and young children was almost nil.

Dr. BLACKADER said that a high mortality in pneumonia was not their experience in Montreal.

Dr. PISEK, in closing, said the empyema cases that succumbed were usually under eighteen months of age and much depended upon the activity of the surgeon. Conservative surgery gave a young child a better chance of recovery.

An Unusual Case of Congenital Heart Disease, with Demonstration of Specimen.—Dr. JOHN LOVETT MORSE of Boston demonstrated this specimen which was taken from a child who died at the age of eight years, and who gave a definite history of cyanosis since the age of four months, but in whom no heart murmur could be detected. This child became ill in November, 1914, with fever, vomiting, change in the blood picture, but with no heart thrill or definite murmur. Dr. Howland saw the case at that time and thought he heard a slight murmur. Later the child developed a diastolic and then a systolic murmur and died suddenly of embolism. The case was diagnosed as "endocarditis implanted on congenital heart disease." The heart showed an opening in the ventricular septum, three patent valves, and a transposition of the great vessels, together with atresia and some malformation. It was said there were only five cases like this on record.

Dr. WILLIAM P. NORTHRUP of New York said that some years ago he had reported a similar case before the New York Pathological Society. He had seen the child during life and the murmur was very mild. It was unusual to find a diastolic murmur in a congenital heart condition, though he had seen one or two children with diastolic murmurs.

Report of a Case of Myelogenous Leucemia in an Infant Nine Months Old.—Dr. JOHN MASON KNOX of Baltimore reported this case in which the symptoms pointed to gastrointestinal intoxication with unusual gastric irritability. The differential count of the leucocytes showed the presence of a large number of myelocytes from the bone marrow and established the diagnosis of acute myelogenous leucemia. The report of the blood examination showed 200,000 leucocytes, a moderate secondary anemia, no marked reduction in the red blood cells and very few nucleated red cells. The platelets were about normal and there was no fragility of the cells. The polymorphonuclears were young, often with scanty granulations and showing all transitions to myelocytes. In his case the atypical granulations seen in the neutrophile myelocytes as well as the presence of eosinophiles and basophilic varieties was good evidence of primary disease of the blood forming agents.

Dr. A. D. BLACKADER of Montreal related the history of a case somewhat similar to that of Dr. Knox.

Dr. KNOX said the lesson to be drawn from these cases was that in a case of persistent nausea and vomiting the blood should be examined early.

The Hydrogen Ion Concentration of the Gastric and Duodenal Contents in Childhood.—Dr. JULIUS PARKER SEGEWICK of Minneapolis presented this paper in which he described the methods usually employed for the estimation of the hydrogen ion concentration and stated that the results presented in this study were obtained by the "gas chain method." The duodenal contents were obtained by the Hess catheterization method. A summary of their work warranted the following conclusions: (1) The results of other observers which showed a low acidity of the gastric contents of infants during the height of digestion were confirmed. (2) The sharp rise of acidity of the gastric contents toward the close of digestion was shown. (3) The gastric contents of a new-born infant before food was taken were very acid. (4) The duodenal contents of infants obtained by the Hess method were not alkaline, but showed a hydrogen ion concentration of 79.5 to 0.9 times 10 minus.

Wednesday, May 26—Third Day.

Report of Committee on Child Labor Problem.—Dr. PHILIP VAN INGEN of New York presented this report in which he related the difficulties that beset the investigator along this line. Little statistical data of value was available. In studying the effects of various occupations on children medical questions had come up for which no satisfactory answers were found, so they had begun an investigation on the subject of fatigue and its results, mental and physical, upon the development of the child and upon the mature organisms. They were studying occupations with reference to mortality, susceptibility to certain diseases and the effects of such occupations in connection with race and heredity. They had collected a great deal of material but still had far to go to get at the facts.

Report of Committee to Cooperate with the Federal Bureau.—Dr. HAMILL of Philadelphia reported for this committee stating that the committee had been consulted in a number of instances by the Federal Bureau on certain subjects upon which they wished to have medical opinion.

Some Interesting Facts Plainly Brought Out by a Chart Method of Studying and Managing Cases of Diabetes Mellitus in Children.—Dr. T. DEWITT H. SHERMAN of Buffalo made this presentation in which he emphasized the importance of charts in furnishing an easy and quick way of giving information concerning a case. The upper half of the charts presented showed in unbroken lines the number of grammes of the three food elements ingested and their total caloric value. The lower half showed in broken lines the urine analyses and hence the condition of the patient on the selected diet. The use of colored chalks brought out other information, as for instance, the number of grammes of carbohydrate ingested and its relation to the amount of sugar in the urine. By the use of this method of charting a case the writer had been led in one case, which was given as an illustration, to the conclusion that sugar in the urine was caused first, by feeding high fats, and second, by mental anxiety. In another case it was shown that fish caused sugar, while all the other proteids were fairly well tolerated. In still another case it was shown that high fats caused cyclic vomiting. Sugar might appear before cyclic vomiting more often than they suspected.

Differential Diagnosis of Stenosis and Spasm of the Pylorus.—Dr. ALFRED HAND of Philadelphia read this paper, in which he stated that there were no more difficult problems in diagnosis than those pertaining to the abdomen in infancy and early childhood. The greater activity of the digestive functions at this age was likely to cause disturbances which closely resembled some one or more of the organic affections. There was a tendency to use the term spasm of the pylorus for gastric indigestion due generally to improper feeding. Still one did meet with cases in which it seems that the vomiting did not depend entirely on gastric indigestion, but that the tonic condition of the pylorus was also present, allowing little if any of the stomach contents to pass into the duodenum. The first case of this kind which came under his care after he had witnessed a pyloroplasty after which the infant succumbed within twenty-four hours, in whom the history was very suggestive of pyloric stenosis, but in whom he was unable to demonstrate a lump anywhere in the abdomen, he followed a conservative course. While the patient pro-

gressed very slowly, nevertheless in the second year the nutrition finally became satisfactory. Following this five other cases came under his attention in which no tumor could be felt though visible peristalsis was present, and these had proven amenable to dietetic treatment. So that he inclined to the belief that the genuine condition itself was amenable to dietetic treatment. Even if one could only keep the weight stationary, the patient was growing older steadily with a possible increase in the chances of surviving an operation, if this should be necessary.

The Differential Diagnosis of Stenosis and Spasm of the Pylorus.—Dr. HARRY DEAVER of Philadelphia discussed this subject from the standpoint of the surgeon. He stated that the symptoms of pyloric stenosis were projectile vomiting, constipation, visible peristalsis and steady loss in weight. The urinary output was diminished. There was no bile in the vomitus. When all these symptoms were present and one could follow the tumor and the *x*-ray confirmed the diagnosis an early operation was indicated. It had been his experience that children stood the operation well and when operated upon early all recovered. A palpable mass was never present in a case of pylorospasm. The operation in an infant was a very delicate one since the walls of the jejunum were very thin. The jejunum should be joined to the stomach with a very short loop or without any loop, as close as possible.

Dr. CHARLES HERRMAN of New York said that it had been stated that the presence of a palpable mass was an indication for operation and yet many cases in which a mass was palpable recovered without operation. Pylorospasm and stenosis were not two distinct conditions but were different degrees of the same condition. The prognosis depended upon the degree of stenosis. Dr. Herrman cited two cases in which he had advised operation, but it was refused and the patients recovered.

Dr. HENRY COIT of Newark related the history of a case in which a diagnosis of pyloric stenosis had been made and confirmed by *x*-ray examination which under careful medical treatment recovered.

Dr. E. E. GRAHAM of Philadelphia said there was a great deal of confusion as to the indications for operation. It seemed best to be guided by the severity of the symptoms.

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Student Meeting, May 5, 1915.

THE PRESIDENT, DR. JAMES C. WILLSON, IN THE CHAIR.

Cardiovascular Poisons; Their Methods and Results.—Dr. ROBERT N. WILLSON in this paper said that to those who knew the heart simply as a muscular pump, the function of which was to supply the various parts of the body with blood, the term cardiovascular poison would mean little more than a drug which caused the heart to misbehave or to functionate badly. It was no very recent discovery that if any human organ was overrich in its nervous supply, the heart was that one. An exceedingly important item of knowledge was that one of the main nervous distributions in the heart was subendocardial. Highly important was also an appreciation of the probability that the cardiac nervous structures entered in greater or less degree into the inception and the discharge of each and all of the main functions of the heart. Three groups of cardiovascular poisons briefly discussed were (1) decomposition of food products. These Dr. Willson believed constituted the causal factor in arterial changes and the hypertension contributing so actively to the cardiac disease of later years; (2) microorganismal influences which make their attack from without, such as syphilis, tuberculosis, rheumatism, so-called, and diphtheria. Frequently children of luetic or tuberculous parentage were found to be the subjects of myocardial or valvular defects. The tubercle bacillus and its toxin also furnished an invariably diseased heart. Much uncertainty attached to the acute rheumatic infection even with respect to its etiology. In diphtheria was experienced nearly 100 per cent. of instances of myocardial involvement. The third class of cardiovascular poisons was that of tobacco and alcohol. Histories of two patients were cited illustrative of tobacco poisoning. It was the author's confident belief that between tobacco and the various forms of food toxemia could be divided the responsibility of the vast amount of arteriosclerosis not attributable to syphilis and old age. Alcohol was said to be almost the twin of tobacco in its anesthetic and narcotic effect. Its lack of value as a food had been demonstrated beyond all peradventure and this lack had been accepted as a working principle in all of the foremost laboratories. It was known that in small doses and in large alcohol in continued use soon depressed and then paralyzed the vasomotor nerves. While it was not known that alcohol produced arteriosclerosis it was known that tobacco did, and that the use of alcohol practically implied the craving for tobacco. Other excesses in food and venery the author said were closely associated with alcoholism and the tobacco habit that tended equally toward sclerotic vessels and myocardial disease. It was impossible, therefore, either to indict alcohol upon the score of directly producing arteriosclerosis, or to relieve it completely of either a direct contributory or an indirect responsibility for much of the rapidly increasing cardiovascular disease. Dr. Willson regarded it as only fair to exonerate the drug alcohol from contribution to the sclerotic total when used by the physician in therapeutic dosage—if there were any such thing. There was abundance of reliable evidence to show that the administration of alcohol lowered the vital resistance to bacterial infections by diminishing the power of the human economy to marshall its phagocytes at will and to manufacture the antitoxins requisite to combat the infections working mainly as toxemias. The only conceivable occasion upon which the drug could assist in a grave toxemia was said to be in such an infection as typhoid fever occurring in a strong, robust individual of high antitoxic resisting power in whom there was a too wholesale destruction of bacteria in the tissues with danger that the patient might poison himself to death through the very process that usually worked the cure. In the vast majority of typhoid patients, however, this danger was not present. There were few physicians, he believed, approximating forty years of age or over who felt that a place remained for alcohol in the pharmacopeia of the well read and conscientious physician, except as an emergency stimulant, and then only in minimal dosage which did not mean a half ounce or an ounce at intervals of a few hours. The physiological effect of alcohol was said to be better comprehended by the lay public than by the average medical man, judging by the tide sweeping over the country. With the recent action of 700 physicians of Pennsylvania standing for the right of a community to determine by vote whether its citizens should exchange health for avoidable cardiovascular disease, he felt the next advance to be the ranging of the national medical body on the side of the disuse of a drug now recognized, in any dosage, to be a cardiovascular nerve and muscle poison, a tissue destroyer and an economic harm. Mention was made of the several forms of clinical and laboratory evidence for and against the use of alcohol in medicine. Three series of experiments were mentioned confirming Dixon's conclusion that the first action of alcohol was a stimulation of the heart. For every statement made ample clinical and laboratory evidence was given of investigators known and trusted as such by the entire medical world. While a study of the cardiovascular poisons was incomplete without the consideration of an excessive production of the internal secretions the author limited himself to a discussion of the three groups nearest to the citizen and the general practitioner.

Dr. H. A. HARE had sometimes regretted that in meetings of American associations the custom of English medical societies of attacking each other vigorously was not carried out. While not his intention in anything he might say to give offence he observed that under the title of a paper on heart disease Dr. Willson had really read an attack upon alcohol as a drug. The first mistake in the paper, if he might be pardoned for saying so, he said, was that of making sweeping statements without the slightest justification for many of them, and some of which were in direct controversion to known laws of physiology and pathology. To state, for example, that in the early stage of the influence of alcohol the drug stimulated the circulation by stimulating the vagus showed an entire ignorance of what every second year student in medicine knew—that the function of the vagus was inhibitory and that in its action it decreased functional activity of the heart rather than increased it. Further, when the statement was made that alcohol produced arteriosclerosis and arterial spasm, and in the same breath the assertion was made absolutely that alcohol depressed the entire vasomotor apparatus, it was difficult to agree with the

author, for it was not easy to see how a drug could produce a rise of blood pressure at the same time that it was producing a lowering of blood pressure by depressing the vascular system in general. It would seem that the reader of the paper was not familiar with that which physiologists and pharmacologists recognized as the true physiological action of alcohol. So far as the circulatory action of alcohol was concerned, Dr. Hare stated that in moderate amounts it did not act as a stimulant or as a depressant, but equalized the circulation. He believed there was no drug possessing physiological power which, if wrongly used, would not also have power to do harm. Reference was made to a recent meeting of the Philadelphia County Medical Society in which the author of one of the papers said that alcohol was always contraindicated in tuberculosis. While Dr. Hare regarded such a statement too sweeping to bear weight, published under certain circumstances he felt it might do harm. While the harmfulness of alcohol in miliary tuberculosis was well known, in fibroid phthisis with cough interfering with digestion, it was claimed that the administration of alcohol was the administration of a food which was burnt up in the body, which loaned energy to that body, stimulated digestion, and which if given in the proper form might even help the patient to expectorate the material in the cavities. What was needed, he thought, was the presentation before the College of Physicians of a paper recognizing that when alcohol was abused it did harm; when used rightly, possessed a definite, specific, and often a very valuable place in medicine. This was true in diabetes mellitus, in which disease in certain cases alcohol burnt up in the body, possessed a distinct food value. Contrary to his understanding of Dr. Willson's dogmatic statement that all researches showed that alcohol decreased the ability of the body to protect itself in certain instances, some time ago Dr. Hare had presented a paper before the Association of American Physicians giving the results of a research showing that in typhoid fever and tuberculosis alcohol in proper doses increased very materially the bacteriolytic action of the blood. The technique by which the studies had been made was according to directions given by Dr. Simon Flexner. Upon one point Dr. Willson and Dr. Hare were agreed—that the crusade which had been made in the profession against alcohol had diminished the size of the dose now given by many physicians.

Dr. H. C. Wood, referring to Dr. Willson's mention of cardiovascular action of drugs, said it was known that a drug might have one action upon the heart and an opposite action upon the blood pressure. Because a drug lowered blood pressure no proof was present that it depressed the heart, and vice versa. Pharmacologists, he said, always separated these two actions and studied the effect of the drug upon the heart as distinct from its effect upon the blood vessels. Had this distinction been made by Dr. Willson he would probably not have compared alcohol to nicotine in its physiological action. Dr. Wood thought it difficult to imagine two drugs more widely different in physiological effect than alcohol and nicotine. Further, he thought Dr. Willson in drawing his conclusions from the experiments quoted, failed to make sharp the distinction between the therapeutic and the toxic dose of alcohol; he had spoken of the secondary results of alcohol as if the depressant effect followed when therapeutic quantities were given; whereas, his understanding was that the depressant results were the effect of toxic doses. While Dr. Willson had quoted Dr. Dixon he had neglected to state Dixon's conclusion that alcohol acted as a foodstuff for the heart. Dr. Wood did not think there was any reliable scientific evidence that the secondary effect of small doses of alcohol was a depressant action upon the heart muscle.

Dr. Willson, in closing, said he was by no means sorry to have his paper combated. He was thus afforded opportunity to reply to one or two misleading statements far more "sweeping" and "irresponsible" than anything he had written. For instance, Dr. Hare had ventured the assertion that he was ignorant of the first principles of cardiac physiology upon the basis of his having made a statement (as claimed by Dr. Hare) that alcohol or any other drug stimulated the heart by stimulating the vagus nerve. What he actually had said was that alcohol caused a stimulation of the cardiac action through its depressant action upon the vagus nerve. The inhibitory action of the vagus upon the heart he thought was known to all. He felt that Dr. Hare by his remark seemed to lay himself open to the suspicion of possible ignorance with respect to the action of the sympathetic nerve when the controlling influence of the vagus was set aside. Again, he had made no such statement as that alcohol produced arteriosclerosis; indeed, absolutely the opposite statement, namely: that there was no final evidence that alcohol produced arteriosclerosis. He had shown that the combination of tobacco with alcohol often resulted in the production of this condition. He had also referred to the fact that the combined action of the two drugs gave a different result from that of alcohol alone. He agreed that Dr. Hare was correct in his belief that the dominant action of alcohol was vasodilator after its first temporary splanchnic-constrictor influence, but he forgot the important fact that vasodilatation also characterized tobacco after its early vasoconstrictor action and became its permanent influence. Evidence obtained from the action of both of these drugs was to the effect that vasoconstriction and the elevation of blood pressure were not indispensable to the production of arterial disease. He regretted Dr. Hare's reversion to the fallacy that alcohol was a food in any true sense of the word. In a recent meeting of the County Medical Society Dr. A. E. Taylor had shown in a most conclusive manner that alcohol was never a food in the true sense; and, that to call it such showed an entire ignorance of the readily available laboratory findings. Dr. Taylor's statement had represented the consensus of intelligent medical opinion on the subject.

Serum Studied in Pregnancy.—Drs. John A. Kolmer and Philip F. Williams presented this communication, which was a study of the specificity of ferments in pregnancy and the mechanism of the Abderhalden reaction (1) by means of local skin reactions; (2) by proteotoxin production *in vitro*. The authors said that aside from the probable clinical value of the methods devised by Abderhalden in the serum diagnosis of pregnancy and various pathological conditions, such as malignancy, tuberculosis, lesions of the nervous system and ductless glands, most interest concerned the question of the specificity of the ferments or antibodies involved and the mechanism of their action. While Abderhalden and many of his pupils had claimed a high degree of specificity for the "protective ferments" and his pregnancy reaction, claiming from the beginning that errors of technique were largely responsible for the failure of others to obtain satisfactory results, the authors said that the dialysis test as now conducted was not especially difficult and that sufficient work had not been done by other investigators who had carefully followed Abderhalden's technique to warrant the claim that other factors than those purely technical might be responsible for the divergent and non-specific results obtained. In giving a summary of Part I, it was stated that a placentin, No. 1, prepared by concentration of expressed placental juice preserved with 1 per cent. glycerin and 0.5 per cent. tricresol and injected intracutaneously yielded skin reactions characterized by erythema, infiltration, and pain in 87 per cent. of pregnant or recently delivered women, and in 66 per cent. of women who had borne children, but who were not pregnant at the time these tests were made. This extract also caused 20 per cent. of the men tested to react slightly. When diluted 1 to 10 with physiological salt solution this extract yielded 80 per cent. positive reactions among pregnant or recently delivered women, and 50 per cent. positive among women who had borne children. A placentin, No. 4, prepared in the same manner as the first extract, except that glycerin was not used in its preparation or preservation, yielded 40 per cent. positive reactions among pregnant or recently delivered women, and 14 per cent. positive reactions among women who had borne children. It is probable that glycerin itself acts as an irritant, especially in the hypersensitive skin of pregnant women. A placentin, No. 2, prepared from the residue resulting from the concentration of expressed placental juice yielded 55 per cent. positive reactions among women who were pregnant or recently delivered. This placentin produced slightly positive results in 20 per cent. of the men tested. A glycerin extract, placentin No. 5, upon cutaneous inoculation yielded 50 per cent. positive reactions among pregnant and recently delivered women. Of several multiparous and nulliparous women tested, all reacted negatively. Extracts of human male and female kidney (nephrins) prepared in the same manner as the placentins produced a number of positive reactions among pregnant, puerperal, multiparous and nulliparous women. The most marked reactions were observed with the extract of human female kidney. A summary of Part II showed that proteotoxins were produced during the Abderhalden

pregnancy reaction, which when injected intracutaneously and intravenously into normal animals produced local and general changes analogous to anaphylactic reactions. Proteotoxins produced in a mixture of human pregnancy serum and human placenta were toxic for normal guinea-pigs. The ninhydrin test with dialysates and intracutaneous and intravenous injections of the sera in the Abderhalden reactions yielded fairly parallel indices of the degree of protein digestion and proteotoxin production. The addition of various tissue substrates other than placenta to human pregnancy serum was followed occassionally by proteotoxin production as shown by intracutaneous and intravenous tests with the serum, but except when a substrate of human kidney was used, the amount of proteotoxin produced was usually much less than that produced in mixtures of pregnancy serum and human placenta. Similar results were observed with inorganic absorbents as kaolin, starch, quartz, etc. It was found that the proteolytic ferments in healthy normal serum might produce small amounts of proteotoxins when tissue substrates were added, and occasionally, and to less degree, with inorganic absorbents as kaolin and starch. Complement in itself, it was found, had no direct relation to the ferments in pregnancy serum. Inactivation of serum probably reduced its digestive power through destruction of normal proteolytic ferment and reactivation of a serum by means of the addition of serum complement increased its digestive power to a slight degree probably by reason of the addition of these normal ferments. In pregnancy serum there were two sets of proteolytic ferments, normal and non-specific, and specific ferments. The former might be released through absorption of the antiferment by means of various non-specific organic and inorganic substances, whereas the latter were released through the absorption of the antiferments by means of the specific protein antigen alone. The authors' experiments suggested also that the protein matrix in the Abderhalden reaction was not only the protein of the serum, but also to some extent that of the tissue substratum itself. While hesitating to report upon the local skin reactions in pregnant and puerperal women until a relatively large number were studied, in view of the contradictory results obtained by others, the authors felt justified in concluding that the reactions were anaphylactic in nature and due to an anaphylatoxin produced by the action of general ferments upon a protein substrate. They did not believe at present that the reaction in the skin test for pregnancy possessed a practical value in diagnosis, certainly not among women who had borne children. According to experiments described in Part II, pregnancy serum contained proteolytic ferments which when rendered active produced toxin substances capable of inducing local and general reactions analogous to those observed by Vaughan, Friedberger, and others and regarded as anaphylatic in nature. The authors' experiments suggested also that in pregnancy serum there were two sets of proteolytic ferments, one composed of normal non-specific ferments and the second of more or less specific ferment. Their experiments were in accord with those of Jobling and Petersen, Plaut, Peifer, Bronfenbrenner, and others to the extent that inorganic substances as kaolin were capable of releasing the normal tryptic activity of a serum probably through the absorption of antiferment followed by the digestion of serum protein. Their work indicated that this action was non-specific and the result of the release of normal proteolytic ferments, whereas the activity of the specific ferments in pregnancy serum were best in evidence in the presence of placental tissue.

X-Ray Treatment of Frostbite.—G. Fujinami, recalling the action of the *x*-rays in relieving the itching associated with many diseases of the skin, and noting that itching is a prominent symptom in frostbite, essayed the use of the *x*-rays in the treatment of the latter condition. His experience comprised twelve cases. He found that in frostbite of the first degree in which there was not much swelling one application of the *x*-rays was sufficient. The itching disappeared within three or four days and later the swelling gradually disappeared. In frostbite of the second degree, in which the swelling was present for a comparatively long time several applications of the *x*-rays were required. Hemorrhagic blisters became dry and fissures and ulcers healed after three or four applications of the *x*-rays.—*Sei-i-Kwai Medical Journal.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Washington State Board of Medical Examiners.

July, 1914.

(*Concluded from page* 466.)

[Answer ten (10) questions only in each paper.]

OBSTETRICS.

1. (*a*) What is placenta prævia? (*b*) What is its frequency? (*c*) Symptoms? (*d*) Diagnosis? (*e*) What would you do if you had a case?
2. (*a*) What is prolapse of the funis? (*b*) What is its cause? (*c*) Diagnosis? (*d*) Danger? (*e*) How would you manage a case?
3. (*a*) What is the placenta? (*b*) At what time does it assume its functions? (*c*) From what is it formed? (*d*) What are its functions? (*e*) What is the channel of communication between placenta and fœtus?
4. How would you deliver a brow presentation?
5. (*a*) What is ophthalmia neonatorum? (*b*) What is its cause? (*c*) Symptoms? (*d*) What are the means of prevention?
6. (*a*) What is the vitellus? (*b*) Allantois? (*c*) Amnion? (*d*) Chorion?
7. (*a*) What is eclampsia? (*b*) What per cent of cases occur in primiparæ? (*c*) What is the prognosis to mother and child? (*d*) What is the condition of the urine? (*e*) What is its frequency? (*f*) If it occurs at eighth month of pregnancy, how should it be managed?
8. (*a*) What is eutocia? (*b*) What is dystocia? (*c*) Name varieties of dystocia?
9. (*a*) What is hydatid pregnancy? (*b*) What is its frequency? (*c*) What are its symptoms?
10. (*a*) What is ectopic pregnancy? (*b*) Give the varieties? (*c*) What is the cause? (*d*) Between what ages does it usually occur? (*e*) What are the symptoms? (*f*) What are its terminations?
11. Differentiate an ovarian cyst, a uterine fibroid and pregnancy at the fifth month.
12. Tell what you know about pelvimetry.

TOXICOLOGY

1. Mention five (5) emetic poisons.
2. Method of conducting autopsy in death from arsenic poisoning.
3. Give one test for discovery of a mineral poison.
4. Differentiate tissue change in poisoning from hydrochloric, sulphuric, nitric and carbolic acid.
5. Give symptoms of acute arsenical poisoning.
6. Give symptoms of mercurial poisoning.
7. Method of examining dead caused by gunshot wounds.
8. Infanticide—(*a*) How determine if child born alive? (*b*) How long did it live after birth? (*c*) How determine criminal violence?
9. What signs manifest on pelvic organs in case of criminal abortion?
10. Post-mortem appearances in death from hanging. (*a*) External; (*b*) Internal.
11. What are the signs of recent delivery (parturition)?
12. Source of meat and fish poisoning.

HYGIENE

1. What are ptomaines. Give usual symptoms of ptomaine poisoning and the most common source.
2. In treating a case of scarlet fever what precautions should be taken to prevent spread of the contagion—by attendants? by yourself?
3. What is sewer gas and how is it objectionable.
4. State period of incubation, date of eruption and limit of quarantine in the following diseases: measles, variola, scarlet fever?
5. Give sanitary methods for the production and marketing of pure milk. Name five diseases that may be caused by impure milk.
6. What is Pasteurized milk? Give some advantages and disadvantages.
7. What do you understand by natural immunity? What is acquired immunity? Give examples.
8. Describe fully the precautions necessary in the care of a typhoid fever patient.
9. Describe two methods of disinfecting a room 20 x 15 x 10 feet, giving the amount of materials necessary

10. Name the requisites of a successful house water filter.

11. Name six diseases to which the habitual alcohol drinker is predisposed.

12. How is malaria communicated? How may malarial districts be made healthy?

ANSWERS.

OBSTETRICS

1. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Frequency:* About once in 1200 to 1300 pregnancies. *Symtoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

Treatment before term: Rest in bed, with or without a *tampon*, will arrest hemorrhage for the time; the sinuses are closed by thrombi, and the case may go on to term or another hemorrhage. The patient should be allowed cold drinks; opium may be used where pain is present. If the hemorrhage is great, it is safer to induce labor at once than to wait. Occasionally no hemorrhage occurs during pregnancy, not even in labor. *Treatment at term:* (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation, turn the child and make the breech engage in the os; or, if the head presents, the forceps may be used, if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child.—(Landis' *Obstetrics.*)

2. *Prolapse of the funis* is the condition in which the umbilical cord hangs down alongside of or in front of the presenting part of the fetus. *Causes:* Malpositions and malpresentations, multiple pregnancy, sudden escape of liquor amnii, too small fetal head, too large pelvis or abdomen of mother. *Diagnosis* is made by feeling the cord through the membranes; it feels like a soft, compressible body with pulsations which are synchronous with the fetal heart. *Danger:* Compression causes death of the fetus. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

3. *The Placenta.*—"The placenta is formed by the fusion and intergrowth of the decidua basalis, which forms the maternal portion of the placenta, and the chorion frondosum, which forms the fetal part of the placenta. As a separate organ, the placenta dates from the third month of pregnancy, and from that time gradually increases in size until the termination of pregnancy. The chorionic villi lose Langhans' layer of cells, and embed themselves into the interglandular stroma of the decidua basalis, and sometimes penetrate the mouths of the small veins. The syncytium also penetrates the endothelium of the decidual arterioles, and large blood sinuses are thus formed. By this arrangement, the fetal and maternal blood, while kept separate, are brought into such close contact that osmosis may readily occur between them, thus permitting the absorption of nutritive material from the maternal into the fetal circulation, the excretion of urea and other waste products of fetal metabolism, the passage of oxygen to the fetus, and the excretion of carbon dioxide from it.

"The *functions of the placenta* may be summed up as follows: (1) It is nutritive, allowing of the passage of nutritive material to the fetus. (2) It is respiratory. Oxygen passes to, and carbon dioxide from, the fetus. (3) It is excretory, allowing the escape of urea and other products of fetal metabolism. (4) It has a glycogenic function. Glycogen is stored in its cells for the future use of the fetus. (5) It is iron storing, by which iron in organic combination is passed from the maternal circulation into the fetal circulation to be stored in the liver cells of the fetus, in order to aid in the formation of new colored blood corpuscles.

"At full term the placenta is a discoidal mass about 7 inches in diameter, two-thirds of an inch in thickness, and weighs about 16 oz. Its fetal surface is smooth and covered by the amnion, and its maternal surface is divided by sulci into a number of irregular areas termed cotyledons. The fetus is attached to it by the umbilical cord or funis, which averages 20 inches in length and half an inch in thickness. It consists of a stroma of Wharton's jelly, embedding the two umbilical arteries and a single umbilical vein. It is covered by the amnion."—(Lyle's *Physiology.*)

4. *Management of brow presentation:* If recognized before the onset of labor, postural treatment may be tried. This consists in placing the woman on that side toward which the fetal face is directed, so as to secure flexion of the fetal head. Failing in this, or if only recognized too late for the above to be tried, cephalic or podalic version may be attempted; or forceps may be applied, chiefly to act as a rotator. If the above do not succeed, symphyseotomy may be performed, and the child delivered by forceps. When all other methods fail, if the child is dead craniotomy is indicated.

5. OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent solution of nitrate of silver, immediately after birth.

6. *Vitellus* is the germinal portion of the ovum with the substance which nourishes the embryo.

Allantois is a fetal membrane; it enters into the formation of the bladder, placenta, and umbilical cord.

Amnion is the inner of the fetal membranes.

Chorion is the outer of the fetal membranes.

7. *Eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. About 75 per cent of the cases occur in primiparæ. *Prognosis* is bad, the maternal mortality being about 30 per cent and the fetal mortality from 50 to 75 per cent. The *urine* contains albumin, is reduced in quantity, and is more toxic than normal. *Frequency,* about once in from 350 to 500 pregnancies. "*The treatment of the attack* consists of the administration of chloroform by inhalation, chloral hydrate (gr. 60) by enema, and the fluidextract of veratrum viride hypodermically (gtt. 15 followed by gtt. 5, repeated frequently enough to keep the pulse at about 60 beats a minute), to control the convulsions, and free purgation by croton oil (gtt. 2, or 3, in sweet oil or glycerine), free sweating by the hot pack, and sometimes depletion by venesection to eliminate the poison. The after treatment consists of free purgation by the salines, restriction of diet, and later the administration of tonics and stimulants. The obstetric treatment is usually noninterference." (*Pocket Cyclopedia.*) Sometimes *accouchment forcé* is indicated.

8. *Eutocia* is normal labor, or one in which there is a vertex presentation and no complications.

Dystocia is difficult or abnormal labor, and includes all cases not carried in the term eutocia.

Varieties of dystocia: These may be classified, according to causation, as follows:

(1) *Anomalies of the expellent forces:* (*a*) Excess—precipitate labor; (*b*) deficiency—delayed or protracted labor and inertia uteri; (*c*) spasm and irregularity—rigid os and cervix, and tetanus uteri.

(2) *Anomalies of the passages:* Pelvic deformities; uterus, developmental anomalies of, atresia of cervix, rigidity of cervix, impaction of cervix, malposition, sacculation, and new growths; stenosis and rigidity of vulva and vagina; hematoma or edema of the vulva; latral abscesses and cysts; conditions of intestines or bladder; tumors and swellings of various tissues.

(3) *Anomalies of the fetus:* Malposition of the head; occipito-posterior cases; malpresentations—face, brow,

pelvic, and transverse; prolapse of limbs; anomalies of fetal development—shortness of cord, unduly ossified skull, large size of fetus, death of fetus, and enlargement of head or body by disease; plural births, and monstrosities (modified from Jewett's *Practice of Obstetrics*).

9. *Hydatid pregnancy* is a pregnancy in which the chorionic villi undergo a proliferating degeneration with the production of a mass of cysts attached to the placenta. These cysts look like bunches of grapes. It occurs once in about 2,000 cases of pregnancy.

The pregnancy begins as in normal cases, but about the third month the uterus becomes suddenly and rapidly enlarged; irregular uterine hemorrhages occur; and there is a discharge of fluid containing the vesicular growths; labor occurs and the mass of cysts is expelled.

10. *Ectopic pregnancy* is a pregnancy where the fetus is being developed outside of the uterine cavity. *Varieties:* It may be interstitial, tubal, ovarian, or abdominal. *Probable cause:* Some pathological condition in the Fallopian tube which obstructs the passage of the fecundated ovum. The most common condition is salpingitis, especially of the gonorrheal variety. The age at which it commonly occurs is not known. King says, "It is more apt to occur after than before thirty years of age"; Dorland says, "It is generally encountered in women who are between twenty and thirty years of age." *Symptoms of tubal pregnancy* will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

The *possible terminations* are: Rupture of the tube, followed by hemorrhage, shock, peritonitis, and perhaps death; tubal abortion, and continuance of the pregnancy to term.

11. *Pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis.

Uterine fibroid: Menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while generally placed somewhat centrally is not in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years.

Ovarian cyst: Absence of the chief signs of pregnancy; there may be the characteristic facies, the tumor is soft, fluctuating, is more to one side, and does not show fetal signs.

12. *External pelvimetry:* "The measurements are made with a pair of calipers. *Interspinous diameter* The points of the calipers are held in the two hands so that the point of the forefinger rests alongside the point of the instrument. The two anterior superior spines are located, and the points placed on them. The calipers are then screwed tight by an assistant or nurse, and the measurement read off. Normally it is 9½ to 10 inches. *Intercristal diameter:* The instrument is held as before and the points passed slowly round the iliac crests until the points of greatest separation are found, when the measurement is made. Normally it is 10½ to 11 inches. The *external conjugate diameter* is measured by placing the one point of the calipers over the tip of the last lumbar spine, and the other over the front of the symphysis pubis. This is most easily done with the patient standing, and the tip of the last lumbar spine can be found by counting downward from above. It is, however, usually marked by a slight dimple due to fascial attachments. In fat persons it suffices to make a point in the mid line 2½ inches above the line joining the posterior superior iliac spines. The external conjugate usually measures about 7½ to 8 inches; 3½ inches at the very least must be allowed for the thickness of the bony and soft tissues. Therefore, while a large reading may not necessarily mean a large conjugate, a reading under 7½ inches, and more especially under 7 inches, indicates that the conjugate is diminished proportionately.

"*Internal pelvimetry:* The *diagonal conjugate* from the promontory of the sacrum to the under margin of the symphysis may be measured by the fingers. The diagonal conjugate measures 4½ to 4¾ inches, and ½ to ¾ of an inch must be subtracted to give the length of the conjugate vera. The actual amount to be subtracted varies with the depth of the pubic bone and its inclination toward the sacrum, so that at the best this method of estimation is but approximately correct. In practice, however, these methods are found to be sufficiently accurate in the vast majority of cases. It should be remembered that in a normal pelvis it is impossible to touch the promontory of the sacrum by vaginal examination without forcing the fingers so far in as to hurt the patient. Therefore if the promontory can be felt readily it indicates a small pelvis and the desirability of more careful investigation. The *outlet of the pelvis* can be directly measured in both its anteroposterior and transverse diameters by means of the fingers and a measuring tape, or more conveniently by means of a pair of calipers with the points crossed."—(Johnstone's *Textbook of Midwifery.*)

TOXICOLOGY.

1. *Five emetic poisons:* Arsenic, antimony, croton oil, mercuric salts, and ptomaines.

2. The following portions of the cadaver should be preserved for analysis in cases of suspected homicide by poison: "The alimentary canal from the cardia to the middle of the rectum, unopened, and the contents enclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder. Any suspected food articles, and any obtainable vomited matter, are to be also preserved. They are to be placed in clean and new glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and cap, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself.

"The post-mortem appearance in acute arsenical poisoning are confined to the stomach and intestines. The stomach is inflamed, whether arsenic has been taken by the mouth or by other channels of absorption. The mucous surface is coated with a layer of mucus, tinged with blood or bile, and sometimes containing white crystals of As_2O_3 or green particles of Paris green. The color of the mucous membrane is brownish red, interspersed wtih darker streaks or patches between the rugæ. The small intestines are sometimes inflamed throughout their length, but more usually the inflammation is limited to the duodenum."—(Witthaus' *Essentials of Chemistry and Toxicology.*"

3. *A reliable test for arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

4. *The tissue changes in poisoning* by the acids mentioned are as follows:

"In *poisoning by sulphuric acid*, the postmortem appearances correspond with the amount of local injury, and this depends upon the size of the dose, state of concentration and length of time after the poison has been swallowed. Spots on the skin are white at first, but soon become brown. The mucous membrane is white and leathery and friable. The heart is generally empty and the venous system engorged with cherry red, thick, ropy, acid blood. The stomach is generally corroded, but may only show indications of severe irritation."

"In *poisoning by nitric acid* the mucous membrane of the mouth and throat is yellow. The stomach is distended with gas, if not perforated, and patches of yellow, brown or green are seen on its internal surface. Perforation is not common."

"In *poisoning by hydrochloric acid* the appearances are much the same as from the preceding acids, but there is not so much disorganization of tissue."

"In *poisoning by carbolic acid* the mouth and throat show corrosive effects. The mucous membrane is gen-

erally white or gray and pultaceous, or it may be hardened and corrugated. The stomach usually shows relatively little corrosion. The blood is dark and fluid."—(*Riley's Toxicology.*)

5. *The symptoms of acute arsenical poisoning:* "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities." (Witthaus' *Essentials of Chemistry.*)

6. *Symptoms of acute mercurial (corrosive sublimate) poisoning:* "The nauseous, metallic taste is experienced during the act of swallowing. Within a few moments this is followed by an intense, burning pain in the mouth, throat and stomach, the mouth and tongue are whitened and shriveled. There are vomitings of a white material, containing shreds of mucous membrane and tinged with blood, and bloody stools. Salivation occurs if life be sufficiently prolonged. Death sometimes occurs early from collapse, accompanied by convulsions, or in the deep coma; but in most fatal cases life is prolonged for from three to six days." (Witthaus' *Essentials of Chemistry.*)

7. *Points to be considered in the investigation of gunshot wounds*, are: "(1) the position of the weapon, whether within the hand of the deceased, or whether it has been so placed by another; (2) the presence or absence of blood upon it; (3) the indication or not of the recent discharge of the weapon; (4) the number of cartridges or bullets discharged; (5) the caliber of the weapon; (6) the weight and dimensions of the ball discharged; (7) the number, size, and direction of the wounds; (8) the presence or not of marks of violence and of blood-stains; (9) the amount of blood lost, whether clotted or not; (10) the presence or not of stains upon the clothing; (11) the direction of the effused blood; (12) the course of the wounds in the body; the presence or not of foreign substances (splinters of bone, fibers of tendon or aponeurosis) in the course of the missile; (13) the condition of the lips of the wound, whether there be inversion of the wound of entrance and eversion of the corresponding one of exit, or not; (14) the condition of the weapon, of its barrel; or if a revolver, of its different chambers; note whether they are clean or not, etc.; (15) the peculiarities, if any, of the cartridges; whether the primer is marked by the hammer, and the name of the maker, etc.; (16) the size and weight of the bullets used; (17) the weight and number, if shot were employed; (18) the condition of the sights of the weapon, whether displaced or loosened, etc.; also note the "trigger-pull," and (19) the places of impact of the various bullets, as upon the wall, etc." (Herold's *Legal Medicine.*)

8. "In addition to the hydrostatic test, *live birth* may be deduced from the following conditions: The stomach may contain milk or food, recognized by the microscope and by Trommer's test for sugar; the large intestines in still-born children are filled with meconium; in those born alive they are usually empty; the bladder is generally emptied soon after birth; the skin is in a condition of exfoliation soon after birth. The organs of circulation undergo the following changes after birth, and the extent to which these changes have advanced will give an idea of how long the child has lived: The ductus arteriosus begins to contract within a few seconds of birth; at the end of a week it is about the size of a crowquill, and about the tenth day is obliterated. The umbilical arteries and vein: The arteries are remarkably diminished in caliber at the end of twenty-four hours, and obliterated almost up to the iliacs in three days; the umbilical vein and the ductus venosus are generally completely contracted by the fifth day. The foramen ovale becomes obliterated at extremely variable periods, and may continue open even in the adult." (Murrell's *Aids to Forensic Medicine.*)

"The criminal modes for the purpose of destroying the life of the newborn child are suffocation, drowning, cold and exposure, starvation, wounds, fractures, and other injuries, luxation and fracture of the neck, poisoning, intentional neglect to ligate the umbilical cord, causing the infant to inhale noxious gases, the introduction of instruments into various parts of the body, etc."

9. There may be marks of violence or injury on the uterus or vagina, such as perforation or tears; but there may be very few signs after the lapse of a very few days. There may be the signs of a recent delivery.

10. *Postmortem appearances in death by hanging:* "In the main they resemble those attending death from strangulation. Externally, swelling and lividity of the face, congestion of the eyelids, dilated pupils, eyes red and protruding, tongue swollen, livid, often protruded, or compressed between the teeth, lower jaw retracted; often a bloody froth escaping from the mouth and nostrils. There are frequently petechial effusions on the neck, shoulders, arms, and hands. In many cases, however, especially in suicides, the countenance is calm, the face pale, the eyes and tongue natural. Sometimes there is turgescence of the genital organs, and an involuntary escape of the urine, feces, and semen, but these signs are by no means peculiar to death by hanging. The position of the head varies according to the part of the neck where the knot was placed. As the latter is usually behind the neck, the head is generally flexed forward. If the knot were in front, the head would be found extended backward (Tardieu). The hands are generally closed, often tightly; the legs extended, and often livid. The neck is nearly always stretched, owing to the weight of the body, and it presents very decided marks of the cord, varying, however, somewhat according to the nature of the latter and its mode of application. Thus, the mark may be deep or superficial, single or double, according to the strain made upon it, and the thickness, roughness, or duplication of the cord. The skin under this mark becomes very dense and tough, and of a yellowish-brown color, and has been aptly compared to old parchment. This appearance is more marked if the body has remained suspended for some hours or days; and the cellular tissue underneath is also condensed, and has a silvery appearance. Besides the above, there is often a livid mark (ecchymosis), where great violence has been used, as in executions; but the latter is quite distinct from the true mark of the cord, with which it has been confounded. The livid line is much less frequently met with than was formerly supposed. The groove or furrow in the neck is oblique (which distinguishes it from strangulation); it may also be double (arising from a double fold of the cord), and irregular or interrupted. It is more marked in front, less so at the sides and below the ears, and ceases behind. In general, the narrower the ligature, and the longer the suspension, the deeper the furrow. A broad leather thong, pressing only by its borders, might produce a double mark.

"Internally the appearances usually accompanying asphyxia are met with, such as engorgement of the lungs, right side of the heart, and venous system, with dark fluid blood. Both ventricles of the heart contain blood, if the death has been caused by apoplexy; if by asphyxia, the left cavities are found empty, while the right side of the heart and the large vessels are engorged with blood. The lining membrane of the larynx and trachea is deeply congested, as in strangulation, and is sometimes coated with a bloody froth, though less so than in strangulation and suffocation. The vessels of the brain are generally congested, but extravasation of blood into the brain or upon its membranes is extremely rare. The brain itself when cut into presents numerous bloody points. The kidneys are usually congested; the stomach frequently presents evidences of such deep congestion as to suggest the idea of an irritant poison. The same is true also of the intestines." (Reese's *Medical Jurisprudence.*)

11. *The signs of recent delivery:* "If the woman is examined within three days of her delivery, the followings signs will be shown: pallor of the face and general weakness will be apparent; the skin will be moist, relaxed, and soft; the eyes somewhat sunken, with a darkening beneath or surrounding them; the pulse will be soft and slightly quickened, and the breasts are knotty to the feel, and full and enlarged; the nipples are enlarged, and often exude a watery-like milk. In addition to these signs the abdomen feels soft and relaxed to the touch, and is thrown into folds; it shows on its surface numerous transverse lines, the lineæ albicantes. The uterus is readily appreciated, between the abdominal walls, being situated low down within the pelvis; it appears like a large ball. The external genitals are swollen, moist and relaxed. The vagina is rather capacious, and there is a mucopurulent discharge from the uterus. The os uteri is patulous and low, the lips thereof being somewhat soft and relaxed, and perhaps lacerated. These signs singly afford no proof of delivery, but when taken together they form conclusive evidence of the recent delivery of the woman." (Herold's *Legal Medicine.*)

12. "The kinds of food which most frequently produce symptoms of poisoning are pork, veal, beef, meat-pies, potted and tinned meats, sausages and brawn. It is not necessary that the food should be "high" to give rise to poisoning. It may arise from the use of the flesh of an animal suffering from some disease, from inoculation with microorganisms, or from the presence of toxalbumoses or ptomaines. Many diseases such as diarrhea, enteric fever, and cholera, and perhaps tuberculosis, may be caused by eating infected foods. Trichiniasis may also be mentioned. Tinned fish often gives rise to symptoms of poisoning, and shell fish are not uncommonly contaminated with pathogenic microorganisms. Mussel poisoning was formerly supposed to be due to the copper in them derived from ships' bottoms, but it is more probably the result of the formation of a toxin during life, and not after decomposition has set in." (Murrell's *Aids to Forensic Medicine.*)

HYGIENE.

1. *Ptomaines* are basic, nitrogenous, organic compounds produced from protein material by the bacteria which cause putrefaction.

Symptoms of ptomaine poisoning: Nausea, pain in abdomen, vomiting, purging, chilliness, headache, thirst, weak and rapid pulse, anorexia, impairment of vision, muscular weakness, collapse.

The *most common source* is decomposed or infected food (meat, sausage, fish).

2. The patient must be isolated; no one but the physician and nurse must enter the room; the physician should put on a large washable gown when he goes in, and remove it on leaving, at the same time washing his hands in a disinfectant; the nurse, when she leaves the sick room should also remove her clothes and put on others, at the same time disinfecting herself. Special care must be taken during the period of desquamation. At the termination of the disease everything should be disinfected; toys, and books, etc., are better burned. And see answer to question 8.

3. The air of sewers (*"sewer gas"*) has no constant composition, and if the sewer be properly constructed, well ventilated, and sufficiently flushed, may differ but little from outside air. Much depends upon the sewage being removed quickly, or, on the other hand, being allowed to stagnate and undergo decomposition. In the latter case the air of the sewer becomes foul; oxygen is lessened, carbonic acid increased, and there is much organic matter, together with variable quantities of marsh gas, sulphuretted hydrogen, and ammonium sulphide. The exact composition of the organic matter varies, but its properties are similar to those of the organic matter in respired air. Micro-organisms adhere to moist surfaces, and hence the air of well-constructed sewers is, on the whole, remarkably free from them, except near fresh air inlets and at junctions, where splashing occurs. Neither bacteria nor other solid particulate matters are, under ordinary circumstances, given off from quiescent liquid surfaces; but if putrefaction be allowed to occur the bursting of bubbles may recharge the air with them. . . . It is probable that pathogenic organisms are but rarely conveyed by sewer gas. Air contaminted by sewage emanations may, however, be a cause of diarrhea and other gastrointestinal disturbances, and of certain forms of sore throat. Anemia, depression, and general ill-health may result from protracted exposure to such an atmosphere. Cholera, enteric fever, pneumonia, erysipelas, puerperal fever, and diphtheria. Cholera, enteric fever, pneumonia, erysipelas, puerperal fever, and diphtheria have a much heavier incidence, both in numbers and severity, upon persons exposed to these conditions. It is not necessary to assume an origin *de novo* in such cases, or even in the case of diarrhea and sore throat, the evidence being consistent with the supposition either that the specific poison is sometimes carried by such emanations, or that their effect is merely to predispose to the disease. There is no evidence of any specific relation between sewer gas and small-pox, measles, or whooping-cough." (Whitelegge and Newman's *Hygiene and Public Health.*)

4. MEASLES. *Period of incubation:* From 7 to 18 days, oftenest 14. *Date of eruption*, third or fourth day. *Quarantine.* In contacts, 18 days; for the sick, at least that length of time, and as much longer as for the entire completion of desquamation and the subsidence of the catarrhal conditions. After release from quarantine the child should not be allowed to re-enter school for at least 5 days longer.

VARIOLA. *Period of incubation*, 9 to 15 days; most often 12 days. *Date of eruption*, usually on the fourth day. *Quarantine.* For the sick, until desquamation is complete and the skin thoroughly healed, not less than 21 days. For contacts, 14 days.

SCARLET FEVER. *Period of incubation*, usually from 2 to 4 days; occasionally 24 hours and sometimes as long as 12 days. *Date of eruption*, first or second day. *Quarantine.* For contacts, 12 days, if possible non-immunes should be isolated in another house. For convalescents, until desquamation is absolutely complete, a minimum of 21 days and a maximum of 8 weeks; with a running ear, the child should be excluded from school much longer than 8 weeks and should under no circumstances return to school under 5 weeks. (From Gardner and Simonds' *Practical Sanitation.*)

5. *Essentials for the production and preservation of pure dairy milk:* Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60 deg. Fahr., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer it must be kept in a clean place, and at a temperature some degrees below 60 deg. Fahr."

Diseases specially liable to be conveyed by the ingestion of milk: Tuberculosis, typhoid fever, scarlet fever, diphtheria, tonsilitis, cholera, and gastrointestinal disorders.

6. *Pasteurization of milk* consists in heating the milk for twenty minutes at a temperature of 140 deg. Fahr.

"Advantages of pasteurization milk (1) That most, if not all, of the common bacteria and their toxins are killed. (2) That the ordinary ferments and germicidal properties of the milk are not destroyed. (3) That the process may be accomplished on a large scale, and furnish a commercially safe milk. (4) That the taste, appearance, odor, and cream separation quality of the milk are not altered. (5) That pasteurized milk, if kept cold, furnishes a clean, healthy milk, safe for infant food and other uses.

"Disadvantages of the pasteurization of milk: The following are some of the objections which are urged by the opponents of pasteurization upon a large and commercial basis: (1) That the spore-bearing bacteria and bacterial toxins are not destroyed, and the milk is therefore not wholly safe. (2) That pasteurization stops lactic-acid fermentation, and thus destroys the only 'nature's danger signal,' and the first symptom by which aged milk is known. (3) That unless pasteurized milk is rapidly cooled and kept under 50 deg. Fahr., certain fermentative changes which are ordinarily stopped by lactic-acid fermentation increase in activity, owing to the destruction of lactic-acid bacilli by the pasteurization. (4) That pasteurization, by preserving unclean milk for some time, may induce the producers to furnish dirty milk, discourage rigid cleanliness, and promote carelessness on the part of the producer who relies entirely on the pasteurization to preserve the milk. (5) That the pasteurization furnishes a 'purified' milk instead of a 'pure milk.'"—(Price's *Hygiene and Sanitation.*)

7. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic microorganisms. Immunity may be either natural or acquired.

Natural immunity is that power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired (1) by

a previous attack of the disease, or (2) by the person being made artificially insusceptible. The conditions which give immunity are: (1) a previous attack of the disease; (2) inoculation with the specific microorganisms in small numbers or of diminished virulence, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Examples. The rat is *naturally immune* to anthrax; the white mouse is *naturally immune* to infection with *Bacillus mallei*. *Acquired immunity* is seen in the immunity from smallpox after vaccination, or after having suffered from an attack of the disease.

8. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes, etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

"When the patient has recovered from an infectious disease, he should be given a general bath with soap and water. In addition to this, he may be bathed with chlorinated soda solution, and in the exanthemata it may be advisable to anoint his body again unless all desquamation has ceased. After a general bath has been given the patient may be allowed to mingle with the well. In most localities the convalescent from certain diseases, especially smallpox, is washed with 1:2000 bichloride of mercury solution, clothed with clean clothing, and then transferred to a disinfected room.

"The clothing and bedding which are to be disinfected by means of steam should be carefully wrapped in cloths saturated with 1 per cent carbolic solution, placed in a wagon, and taken to the disinfecting station. After the bed has been stripped, all refuse matter, paper, and articles of little value are wrapped in cloths saturated with carbolic acid and burned in a stove or furnace. The floor, doors, windows, furniture, and the walls for a distance of 1½ meters from the floor should be washed with 5 per cent carbolic acid solution. The walls and ceiling of the room should subsequently be sprayed with 1:1000 bichloride of mercury solution. If the walls are papered, it is advisable to remove carefully the paper before beginning the disinfection. The room is then closed as tightly as possible and disinfected by means of formaldehyde." (Bergey's *Hygiene.*)

9. To *fumigate by chlorine:* For 1000 cu. ft. of space pour two ounces of H_2SO_4, and three ounces of water, previously mixed and cooled, upon eight ounces of NaCl and two ounces of MnO_2. The fluids must be mixed slowly and with care, and the salts should be in an earthen vessel upon a bed of sand. The generating apparatus should be as high in the room as possible, because chlorine gas is very heavy.

To *fumigate by sulphur dioxide:* For each 1000 cu. ft. of space, five pounds of sulphur are burned, care being taken to prevent accidents. In all cases, all apertures and crevices of the room should be closed, all closets, drawers, or other receptacles opened; and after the fumigation the room should be well ventilated and thoroughly cleansed with a solution of corrosive sublimate.

The room in question contains 3000 cu. ft.

10. *The requisites of a good filter* are (according to Parkes): (1) That every part shall be accessible for cleansing or renewing the medium. (2) That the filtering medium shall have a sufficient purifying power and be present in sufficient quantity. (3) That the medium gives nothing to the water favoring the growth of low forms of life. (4) That the purifying power be reasonably lasting. (5) That there be nothing in the construction of the filter itself capable of undergoing putrefaction or of yielding metallic or other impurities to the water. (6) That the filtering material shall not clog, and that the flow of water be reasonably rapid; to which may be added: 7. That the filtering medium be such that it can be readily cleansed and sterilized, or else so cheap that the removal and replenishing may not be neglected when necessary on account of the expense.

11. *The habitual use of alcohol predisposes to:* Arteriosclerosis, chronic nephritis, cirrhosis of liver and kidneys; it lowers the resisting power against bacterial invasion, hence pneumonia, tuberculosis, etc., may be included in this list. The excessive use of alcohol shortens life; the moderate use probably has no effect on longevity, but much depends on the constitution and habits of the individual.

12. *Malaria* is transmitted through the bite of an infected mosquito (*anopheles*). Individuals should use mosquito netting round their beds and wire gauze in doors and windows, so as to keep out the mosquitos as much as possible. All pools, stagnant water, etc., where mosquitos may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumagation with formaldehyde or sulphur is also efficacious.

Therapeutic Hints.

For Callosities.—The following is said to be efficient:

℞ Resorcin.
Salicylic acid, āā 1 gram.
Lactic acid.
Flexible collodion, āā 10 grams.

S.: Apply daily for five or six days; then after a foot bath employ friction over the callous part and pick off the collodion with the loosened callous skin. —*Riforma Medica.*

Ether, Camphor, and Guaiacol in the Treatment of Bronchopneumonia in Infants.—Marfan recommends hypodermic injections of the following solution:

℞ Sterilized olive oil, 8 c.c.
Sulphuric ether, 2 c.c.
Camphor, 0.5 gram.
Crystallized guaiacol, 1 gram.

One cubic centimeter of the above contains 5 centigrams of camphor and 10 centigrams of guaiacol. Up to six months of age the dose is one-quarter or one-third of a cubic centimeter; from six months to two years, one-half of a cubic centimeter; after two years, 1 cubic centimeter. Two injections may be given daily.—*Le Nourrisson.*

Treatment of Paroxysmal Vagotonia.—M. D. Danielopolu proposes this name for a syndrome, characterized by violent vertigo, expulsive vomiting, and attacks of bradycardia occurring in an individual who otherwise shows no sign of any cardiac lesion. The etiology is unknown; the pathogenesis is supposed to be a paroxysmal excitation of the vagus nerve. The treatment advised is the administration of atropine sulphate in doses of 0.0005 to 0.001 gram one-half hour before meals.—*Presse Médicale.*

The Vaccine Treatment of Typhoid Fever.—Francesco Boselli treated twenty patients suffering from typhoid fever by means of intravenous injections of Löffler's vaccine, or subcutaneous injections of the Pfeiffe-Kolle vaccine or the sensitized vaccine of Besredka. The mortality was 15 per cent. in comparison with the mortality of 20 per cent. in the cases not treated with vaccines.—*Il Policlinico.*

For Habitual Vomiting in Nurslings.—Marfan is credited with the following:

℞ Tincture of belladonna, 10 drops.
Sodium bromide, 1 gram.
Sodium bicarbonate, 1.5 grams.
Distilled water, 60 grams.
Simple syrup, 30 grams.

M. et Sig.: Four teaspoonfuls a day from birth up to three months; six teaspoonfuls a day from three to six months.—*La Pediatria.*

SCHOOL-SPREAD OF CONTAGIOUS DISEASES AND HOW TO CONTROL IT.*

BY MYER SOLIS-COHEN, A.B., M.D.,

PHILADELPHIA.

THE complacency with which physicians and public health officials regard the prevalence of the minor contagious diseases, and even sometimes of scarlet fever and diphtheria, is a matter for wonder if not for shame in this enlightened day of preventive medicine. So great is the helplessness and pessimism of most sanitarians as to our ability to limit the spread of the minor contagious diseases, that they make no serious attempt to study how to control it. At the same time they very properly regard as a disgrace the occurrence of a single case of typhoid fever, because they recognize that it can and should be prevented. If some of our statisticians would only show us the monetary loss caused by measles alone, as they have shown us in the case of tuberculosis, perhaps we might realize that it also is a disease whose prevention is worthy of consideration. The number of deaths from measles, or from its complication—pneumonia—is fairly well known. Some have even estimated the frequency of another of its complications—otitis media, which often goes on to mastoid disease, operation, and death. The cost in loss of services through death and disability and the actual expense of physician, surgeon, nurse, hospital, undertaker, etc., can be calculated without difficulty. Another economic loss, which no one seems to realize, is the frequent failure of promotion owing to a five weeks' absence from school when a secondary case occurs in a house, especially should a second absence from a minor contagious disease occur during the same term. This loss of a year's schooling means that one begins one's life's work either a year later or with less education than would otherwise have been the case. The resultant loss in efficiency expressed in dollars would reach a very high figure.

It is, of course, true that by various restrictive public health measures and by medical inspection of public schools an attempt is made to limit the spread of the minor communicable diseases. But when all this fails to prevent widespread epidemics, no one seems very much disturbed or makes any serious effort to study why our present measures fail.

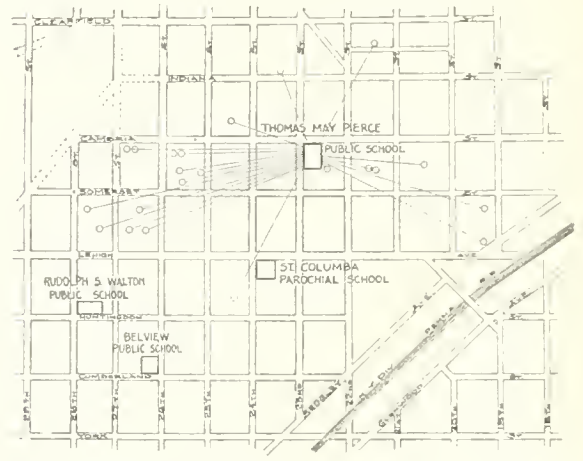
The school has always held an important place among the recognized sources of contagion, but I doubt if many realize how great a factor it really is in the spread of contagious disease. There can be little question that the vast majority of minor contagious diseases are contracted in school. A study of an epidemic in a classroom or in a school or in a city will show that the disease spreads from child to child in a room, from room to room in a school, from school to school in a city. And I am firmly convinced that an epidemic can be checked in a room, checked in a school, and checked in a city. In my papers on "Latent Diphtheria, a Public Health Problem,"[1] and "Diphtheria Carriers; Their Isolation and Control,"[2] I showed how diphtheria spreads in schools, institutions, and dwellings, and how it can be checked. In a more recent paper, "Reporting of Suspicious Cases by the Laity a Prerequisite to the Efficient Control of Communicable Diseases," read before this section two years ago, I described several epidemics of scarlet fever, showing how they originated in unrecognized cases. Dr. Walter N. Roach of Philadelphia, in a paper on "The Rôle of the School in the Spread of Scarlet Fever," presented a diagram map (which I have reproduced) tracing twenty-two cases of scarlet fever to one school of eighteen hundred pupils, although many of the infected children lived at some distance from this school and nearer four other schools with forty-five hundred pupils, not one of whom developed scarlet fever.[3]

Study of a Measles Epidemic.—To show how the minor diseases spread, I have made a study of the epidemic of measles that occurred in Philadelphia during the fall of 1910, the winter of 1910-1911 and the spring of 1911. I have prepared a series of shaded maps showing the location of the cases at monthly intervals during this period. The records on which these maps are based show that the epidemic began—not throughout the city with the opening of schools—but in the week ending October 15, 1910, in one ward, spreading two weeks later to a contiguous ward, and three weeks later to another contiguous ward. During that week twenty-four cases were reported from three contiguous wards and only fifteen cases from the rest of the city. The next week this area extended, four contiguous wards having thirty-seven cases and the rest of the city having twenty-seven. The following week ninety-seven cases were reported from six contiguous wards; sixty-two from the ward where the epidemic started, while throughout the rest of the city there were forty-eight cases. Of the one hundred and fifty-six cases reported the next week, eighty-eight were from these same six wards, thirty from the original one and twenty-nine from one next to it. The epidemic was also beginning to spread to other parts of the city, two wards some distance away having eight and nine cases respectively, and one a little nearer having eight cases. The next week the six original wards and four other contiguous wards had a total of ninety-five cases. Included in the latter was one of the three wards to which the epidemic had spread the previous week. Another had a total of forty-nine cases, while from

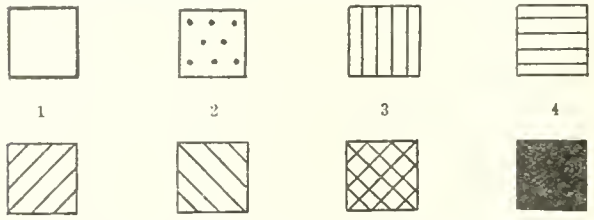
*Read before the Section on Public Health of the American Medical Association, June 10, 1914.

the third and from four wards adjacent to it thirty-two cases were reported. From the other thirty-one wards only forty-seven cases were reported. The

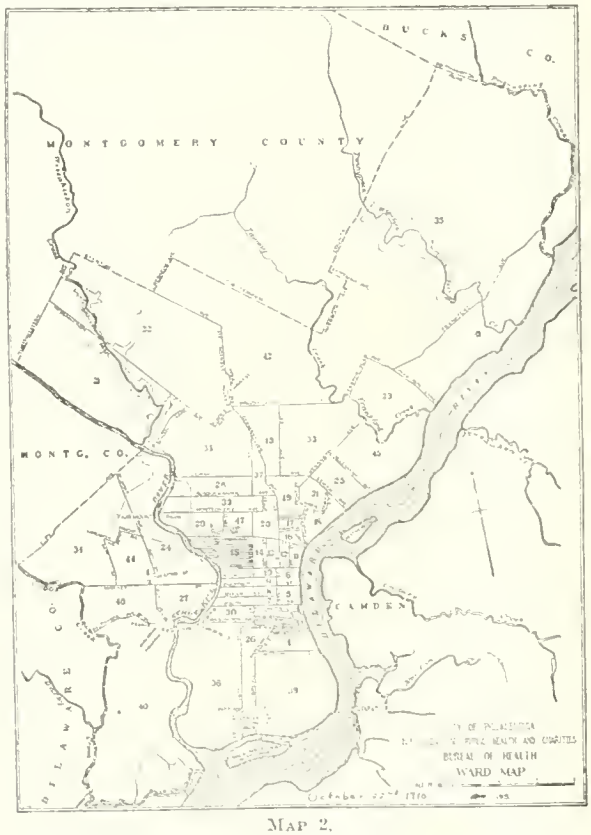
DIAGRAM MAP SHOWING SPREAD OF SCARLET FEVER



MAP 1.—The small circles locate houses of scarlet fever patients. The lines of contact leading direct to the Pierce School as a focus; no other cases occurred in any families or in pupils attending other public or private schools in this territory. (W. N. Roach[4].)

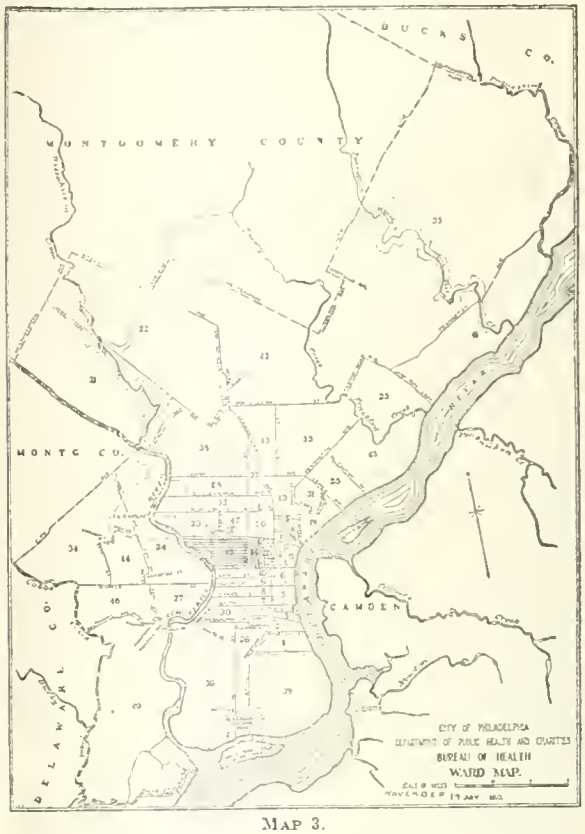


KEY TO MAPS.—1, less than 3 cases in a ward; 2, between 3 and 5; 3, between 5 and 10; 4, between 10 and 20; 5, between 20 and 30; 6, between 30 and 40; 7, between 40 and 50; 8, over 50.



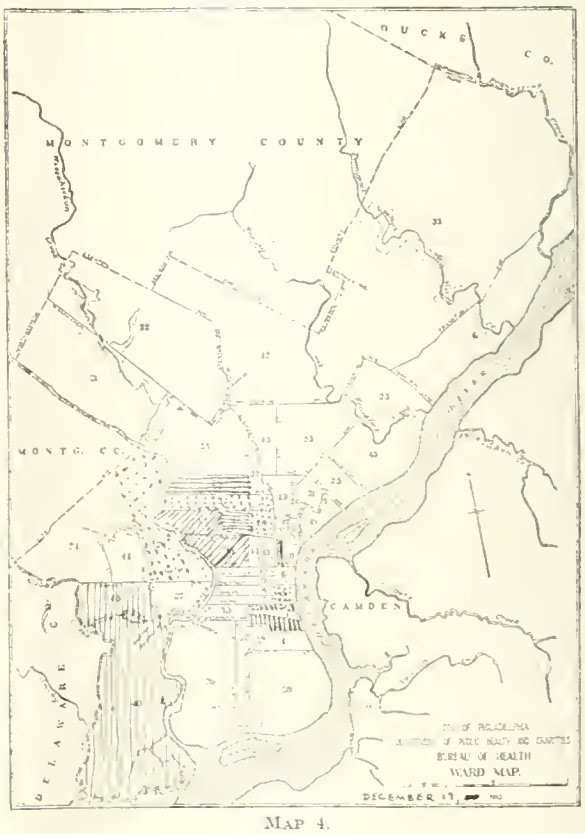
MAP 2.

original ward and six adjacent wards had one hundred and six cases the following week, and three wards in the second focus of infection had seventeen cases. There were seven cases this week, however, in a West Philadelphia ward, separated by the Schuylkill River from the original ward, and seven



MAP 3.

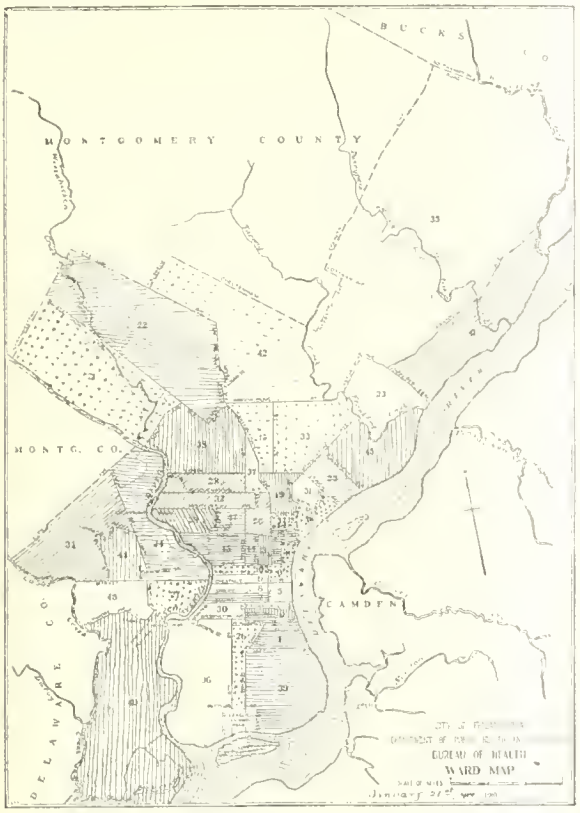
and nine cases, respectively, in two wards adjacent to it. The rest of the city had only forty-one cases.



MAP 4.

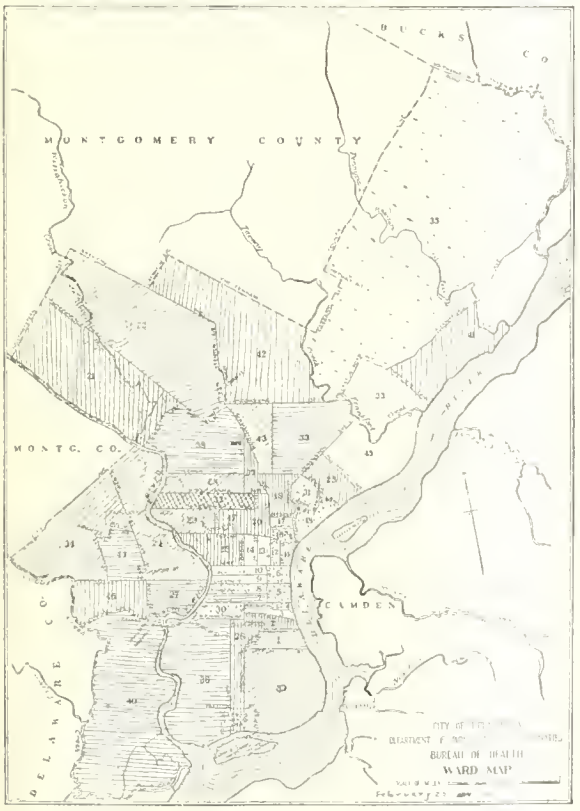
Two weeks later the original focus, now comprising nine wards, had one hundred and thirty-eight cases, the second focus of six wards had fifty-two cases,

and the West Philadelphia focus of three wards directly west of the original ward had a total of fifty-three cases. A spread to the territory east of



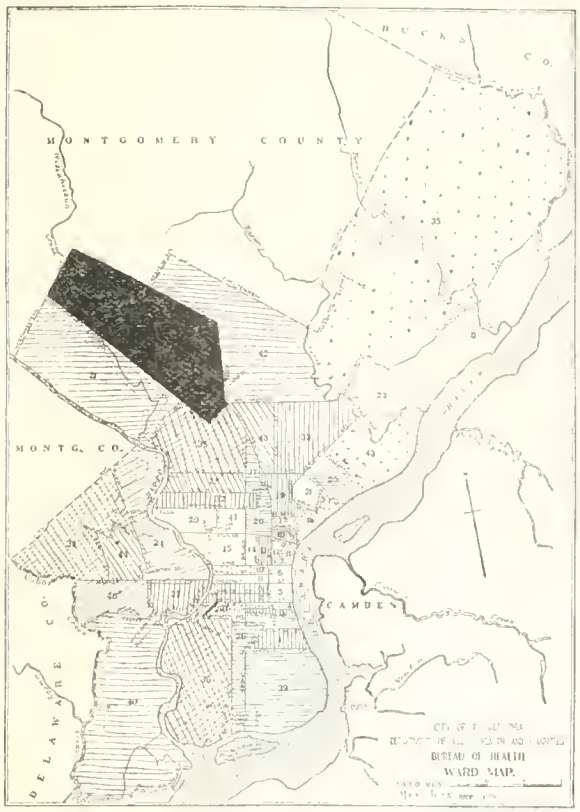
MAP 5.

the original focus and north of the second focus was now beginning, thirty-two cases being reported from



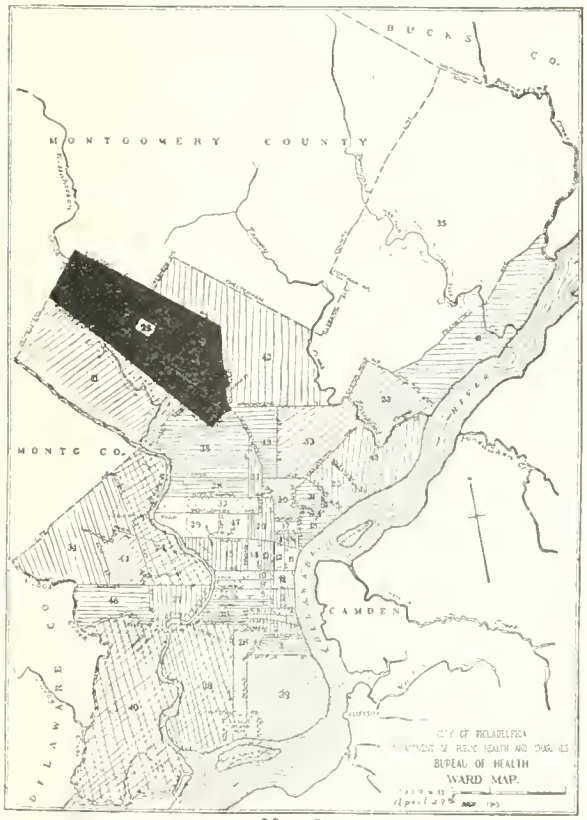
MAP 6.

three wards in this section. There was a general increase also throughout the city, seventy-nine cases being reported from the remaining twenty-six wards. The spread then increased in the second focus of infection and in West Philadelphia and in the northeast section. At the end of four weeks



MAP 7.

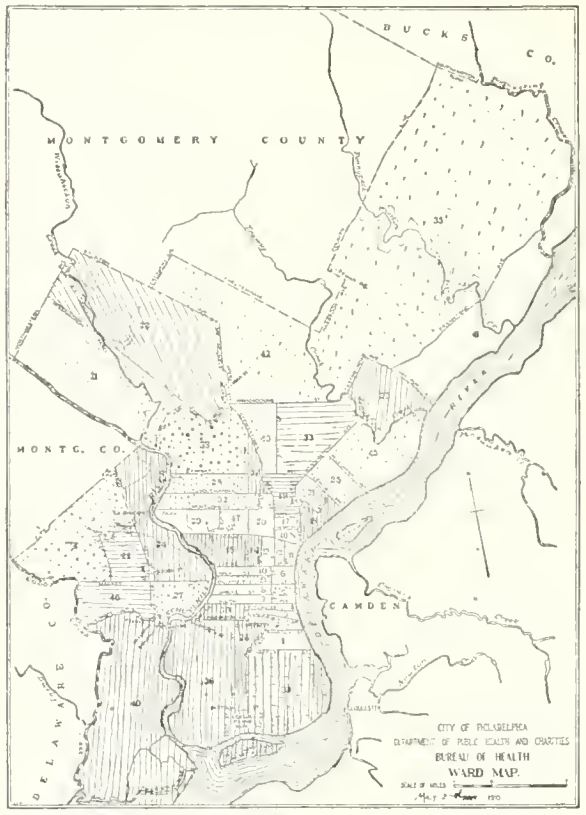
there were one hundred and fifty-six new cases in the original area, now comprising ten contiguous



MAP 8.

wards, sixty-two cases in four contiguous wards at the second focus, which had spread to half the southern section of the city, seventy-two in the three

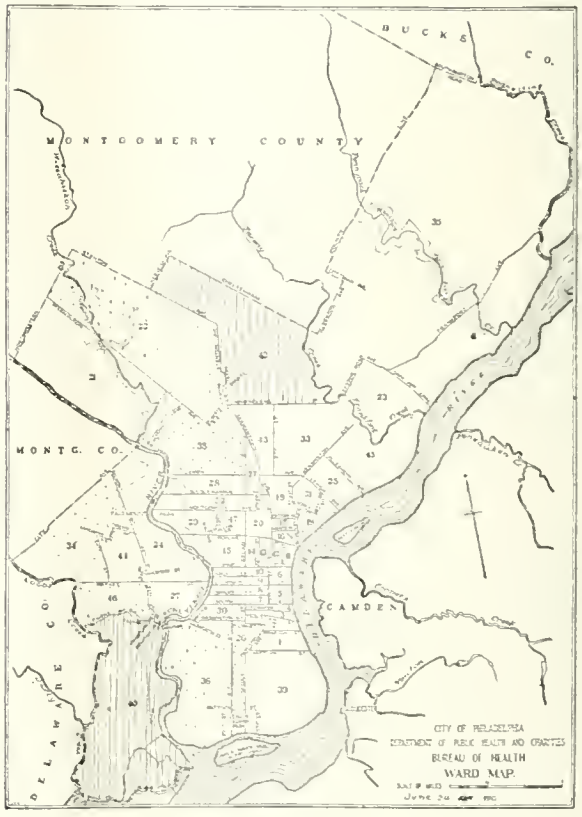
West Philadelphia wards, and seventeen in two wards below them, and one hundred and nineteen new cases in eight wards east and northeast of the



MAP 9.

original focus. The epidemic had also spread to the northern section of the city, forty-four cases being reported from two wards. The other eighteen wards had a total of forty-two new cases. At the end of another four weeks only one case was reported from the original ward, although eighty-nine cases were reported from five contiguous wards above it. The second focus included nearly the whole southern section of the city, ninety-five cases being reported from nine wards. One hundred and sixteen cases were reported from six contiguous wards on the eastern boundary of the original area, eighty-five cases from the five West Philadelphia wards, and seventy from the two wards bounding the original area on the north. Sixty-two cases were reported from the other nineteen wards. Four weeks later the epidemic was diminishing in the original area, except at the northern end, where three wards had a total of ninety-three new cases. The second focus had spread in its southern section, five wards having a total of one hundred and three new cases. One hundred and forty-seven cases were reported this week from West Philadelphia, one hundred and fifty-two cases from seven northeastern wards, and one hundred and forty-four cases from four northern wards. One hundred and two cases were reported from the other twenty-three wards. At the end of another month the epidemic had partially left the section where it had begun. Four contiguous wards to the north and northeast of it had a total of one hundred and eighteen new cases. There was a decline in the wards on the eastern boundary of the primary district, but nine contiguous wards to the east and north of these had one hundred and fifty cases. The second focus now included nine contiguous wards in South Philadelphia, which had a total of one hundred and sixty cases. One hundred and sixty-nine cases were reported from West Philadelphia this week. The other twenty wards had a combined total of seventy cases. The epidemic then began to diminish, there being a drop of about a hundred and fifty cases during each of the next two weeks, of about a hundred cases the following week, and of about ninety the week after. During this week ending May 27, 1911, four contiguous wards in South Philadelphia had a total of thirty cases, four of the West Philadelphia wards had sixty-nine cases, four contiguous wards in the northeast had a total of fifty-nine cases, one ward in the northwest had thirty-one cases, and the ward where the epidemic began had ten cases. The remaining thirty-three wards had in all but eighty-nine cases. Two weeks later only two wards had more than eight cases, one in the northwest with twenty-one and one in West Philadelphia with eleven. After another fourteen days but sixty-nine cases were reported from the entire city, and a week later, that ending July 1, this had dropped to twenty-eight.

The Role of the School in an Epidemic.—The course of an epidemic in being confined at its inception to a small district and then spreading by contiguity is explained by the infection of a school and the transmission of the disease by infected scholars of this school to other members of their families or to playmates, who attend neighboring schools. But just as not all wards become infected in a city epidemic, all schools in a ward do not necessarily become infected. I have prepared a chart of a small epidemic of measles occurring last year in a West Philadelphia ward showing the incidence in the different schools attended by the children of this



MAP 10.

ward. I have also made a map showing the location of those schools. The epidemic began the week of January 14 and ended the week of April 29. Of

the sixteen schools there were no cases in four, one case each in two, three cases in one, seventeen cases in each of two, twenty cases in one, forty-five cases in one, and fifty-nine cases in one. This refers only to the reported cases, which represent possibly one-fourth or less of all the cases that occur. The figures which I have arranged by weeks, consequently do not show so well the way I have found disease to spread in a school, especially as they refer to the weeks in which the disease was reported and not

in which the onset occurred. What I have found practically is that one case appears in a class and at the end of the period of incubation several secondary cases occur, and at the end of another period of incubation another group of cases occur. To show this and also the interval between the date of onset and the date of report, as well as the relation between the date of onset and the last day in school, I have tabulated the nine cases of measles reported from a small private school in which many more cases occurred. Although these occurred in children of the better class, one was in school the second day of the disease, six were in school on the date of onset, and two on the day before. One case oc-
